[a]Hypoglycemia may be delayed, commonly occurring in the early hours of the next morning or after breakfast next day.

in hepatic failure, suppression of hepatic glucose production by alcohol, reduced glycogen stores as in malnutrition, and rare glycogen storage diseases; impaired insulin clearance as in liver or renal failure, hypothyroidism or high levels of insulin-binding antibodies (less common in the present era of purified insulin preparations, although a potential problem with analogues of insulin that have significant immunogenic differences from endogenous insulin); primary loss of counter-regulatory hormones as in Addison's disease, hypopituitarism and isolated growth hormone deficiency; and drugs that interfere with endogenous glucose production. In research studies in people with T2DM, where treatment includes but is not exclusively insulin, a history of smoking, lower educational attainment, cognitive function, presence of microvascular disease were all associated with increased severe hypoglycemia, and in one study of hypoglycemia in people on insulin, there was a correlation with socioeconomic status [46,47]. Outside diabetes, hypoglycemia may be a marker of severe illness and elderly people with diabetes and comorbidities are particularly high risk. Drug interactions causing hypoglycemia are more of a problem with people with residual insulin secretion that may be stimulated by agents such as sulfamethoxozole or using oral hypoglycemic agents than with insulin treatment.

Many studies where patients have been randomized to intensive versus conventional or less intensive treatments have shown greater frequency of severe hypoglycemia in the intensive treatment arms. Nevertheless, modern methods of supporting patients in achieving improved diabetes control using structured education can deliver improved glycemic control with reduced risk of severe hypoglycemia (e.g. [12]), and large recent observational studies show greater severe hypoglycemia in those with less efficient control [48]. It may be that unsuccessful attempts to lower HbA1c carry most risk.

Consequences of hypoglycemia

An acute hypoglycemic episode can present as a neurologic insult, such as confusion, coma, or seizure but recovery after restoring the blood glucose (or after spontaneous recovery of the blood glucose as active insulin wanes and counterregulation kicks in) is usual. There may be amnesia for the event and musculoskeletal injury can occur as a result of unconsciousness or seizure. Rarely, after nocturnal hypoglycemia, a unilateral paralysis mimicking a stroke may occur (Todd's paresis) from which recovery occurs over minutes or hours.

Death from hypoglycemia is difficult to quantify and recent assessments of its frequency range from 4–10% of deaths in people with young-onset type 1 disease, presumably the group most at risk. Using the same data, Kerner and Voltze estimated a mortality rate from hypoglycemia of 0.65 per 1000 people, assuming a mean duration of diabetes of 50 years [49]. In insulin-treated type 2, mortality from hypoglycemia is more difficult to quantify. Increased mortality in a randomized

controlled trial of very intensive glycemic control in people with late T2DM and existing cardiovascular disease was associated with increased risk of both severe hypoglycemia and mortality but the link may reflect that hypoglycemia is a marker for higher risk of mortality [46]—a well-evidenced link that may also explain higher mortality in people with T2DM and lower HbA1c whether or not they are on insulin [50].

The common result of a hypoglycemic episode is recovery. In adults, there is little evidence for permanent injury, including cognitive impairment, from hypoglycemic episodes from which an apparently full recovery is made at the time. Cognitive decline has been linked to hypoglycemia but the direction of that link remains debatable, and any relationship is complex [51]. Similarly in T1DM, hyperglycemia rather than hypoglycemia seems to have the stronger association with cognitive impairment [52]. Patients with problematic hypoglycemia may complain of memory deficits. In animals rendered profoundly hypoglycemic hippocampal injury is described and lesions there would affect memory, but it is equally likely on present evidence that the patient is aware of acute effects of hypoglycemia. Memory is not made during hypoglycemia and may not be consolidated during nocturnal episodes. People in the intensive arm of the American Diabetes Control and Complications Trial (DCCT) had better performance on cognitive function tasks years later than those who had been randomized to conventional therapy, despite a much higher incidence of severe hypoglycemic episodes in the latter and this lack of association between severe hypoglycemia and cognitive performance has persisted in later follow-up [53].

In children, severe hypoglycemia, especially if associated with seizure, is associated with measurable impaired function of some cortical domains in later life. Recent studies continue to show mild loss of certain domains of intellectual and cognitive performance in people who have had T1DM, complicated by severe hypoglycemia, in early life, at a time when brain growth is very active (e.g. [54]).

Hypoglycemia may precipitate a cardiac arrhythmia and this is thought to be the agonal event in rare cases of "dead in bed," a tragic scenario in which a person with T1DM, often young, is found dead in an undisturbed bed. Lengthening of the cQTC interval on the ECG has been seen in both experimentally induced and coincidental clinical hypoglycemia and this is a pro-arrythmogenic change. It is associated with the fall in potassium seen with insulin-induced hypoglycemia, and the stress hormone response and can be prevented in an experimental setting by potassium replacement and by beta-blockade [55]. Hypoglycemia is associated with a pro-inflammatory response which includes a hypercoagulatory state. It has been suggested that this may contribute to vascular complications of diabetes, although there is no epidemiologic evidence for this. Vascular complications were reduced during intensive treatment of T1DM in DCCT, despite the higher rate of severe hypoglycemia. In contrast, it may well be that a hypoglycemic event could precipitate an acute myocardial infarction—in the elderly, presentation of severe hypoglycemia is not uncommonly complicated by myocardial infarction or stroke [56].

Socioeconomic impact of hypoglycemia is difficult to quantify and not many studies have restricted themselves to T1DM or insulin-treated diabetes alone. One web-based questionnaire study describes significant socioeconomic impact of nonsevere hypoglycemia associated with a range of diabetes treatments, but also notes very different experiences between different Western cultures [57]. Other studies have failed to find any quality of life impact of nonsevere hypoglycemia. Nevertheless, fear of hypoglycemia remains potent and may interfere with both patient and healthcare willingness to push for tight glycemic control to reduce long-term vascular complications [58].

In contrast, severe hypoglycemia can have significant impact. Injury may occur with unconsciousness or seizure, loss of cognitive function at work may place the patient and others in danger or create embarrassment as the hypoglycemic person loses intellectual control. Severe hypoglycemia and impaired awareness of hypoglycemia can cost people work opportunities and privileges such as a license to drive and impaired quality of life has been reported in a diverse group of people with T1 and T2DM through an online questionnaire [59]. Type 1 patients with impaired awareness report various negative impacts on their lives [60] and one recent study of a small group of people with T1DM and intractable problems with impaired awareness of hypoglycemia and recurrent severe hypoglycemia reported significant stress in their relatives [61]. The cost to the health economy of severe hypoglycemia is not fully explored, as estimates rarely include time off work or costs other than those associated with the immediate event. Even so, a minimum cost has been quoted as in excess of £13 million in the UK [47].

In rare cases, *automatism* is reported. Automatic behaviors are usually nonpurposeful movements such as lip smacking and associated with epilepsy, but can be more complex, in which the person carries out more sophisticated behaviors with no awareness or recollection afterwards. In this context, automatism is a legal term, implying loss of voluntary control of behavior. In British law, use of this defense to excuse, for example, a driving accident, will depend on being able to prove that the person had no opportunity to take preventive action—for example eating after administration of insulin, or absence of knowledge that he/she had unawareness of hypoglycemia; in current European law, hypoglycemia unawareness is a barrier to having a license to drive [62].

Nocturnal hypoglycemia

In a large glucose-monitoring study of people with T1DM, nocturnal hypoglycemia in people with T1DM complicated about 5–10% of nights [63]. Nocturnal hypoglycemia is, at least 50% of the time, asymptomatic. Studies documenting its frequency continue to report this, despite major changes in insulin regimens and methods of glucose monitoring. As mentioned earlier, in deep sleep, counterregulatory responses to hypoglycemia are significantly attenuated [29], with many episodes being prolonged, and the idea that hypoglycemia at

night is a common cause for fasting hyperglycemia next day (a reinterpretation of the Somogyi phenomenon) is rarely, if ever, correct. The closest association of a nocturnal hypoglycemia is a fasting (pre-breakfast) glucose of less than $5\,mmol\,L^{-1}$ [64]. Although variability of fasting glucose may be associated with risk of nocturnal hypoglycemia, the likely cause of a high pre-breakfast glucose reading is loss of insulin action, perhaps associated with a dawn phenomenon (a rising insulin requirement driven by diurnal variation in hyperglycemic hormones such as growth hormone and cortisol).

Nocturnal hypoglycemia may be associated with reduced mood next morning (although there is no evidence for cognitive impairment), failure to consolidate memory during the day, and reduced responses to hypoglycemia next day [65].

Drivers of nocturnal hypoglycemia include exercise during the day, especially if unusually (for that person) vigorous or prolonged, attributed to depletion of liver and muscle glycogen stores; increased alcohol consumption suppressing gluconeogenesis; and, in insulin-deficient patients, use of conventional rather than analogue insulin [66].

Addressing hypoglycemia in insulin therapy

Hypoglycemia occurs whenever circulating insulin concentrations exceed requirement. The aim of exogenous insulin therapy is to approximate normal physiology but exogenous insulin is not delivered directly to the liver and is not under endogenous homeostatic control.

Assessing a person with diabetes for hypoglycemia experience and risk

Every person using insulin or insulin secretagogues should be made aware of their risk of hypoglycemia and advised about its avoidance, while not engendering inappropriate fear. An assessment of both hypoglycemia experience and risk for severe hypoglycemia should be made at least at annual review and for someone with insulin-deficient (all type 1 and late type 2) diabetes at every therapeutic encounter. Patients may define their events very differently from the healthcare professional, describing as severe an unpleasantly symptomatic episode, which poses a lower health risk than do asymptomatic episodes. People should be specifically asked about their experience of hypoglycemic episodes for which they required help (severe hypoglycemia), documenting the time of day, possible precipitants and outcomes of each one since the last visit; and likewise documenting frequency and timing of episodes that they recognized and treated themselves (Table 53.2). Nocturnal episodes and night sweats that might represent otherwise unrecognized hypoglycemia should be documented, with other causes of night sweating (e.g. chronic infection, disseminated malignancy and lymphoma, autonomic neuropathy, thyrotoxicosis, an overly warm environment) considered. Asymptomatic hypoglycemia is best described by patients' relatives but can be detected by asking about episodes where other people tell the patient he/she is hypoglycemic before they have recognized it for themselves or by coincidental home blood glucose measurement. Again, if present, frequency and high-risk time of day should be documented. Qualitative assessment of hypoglycemia awareness should also be made, using one of the questionnaires validated in terms of usefully predicting severe hypoglycemia. The Gold score [67] simply asks the patient to rank their hypoglycemia awareness from always aware (1) to never aware (7) and defines impaired awareness as a score of 4 or more. The Clarke score [68] is a more complex questionnaire which includes data on frequency of severe hypoglycemia, frequency of episodes of exposure to hypoglycemia with or without symptoms, and the glucose concentrations perceived as hypoglycemic. Another simple question which has validity in terms of being associated with severe hypoglycemia risk is to ask whether the patient is aware of hypoglycemia at glucose concentrations of $3\,mmol\,L^{-1}$ or more, under $3\,mmol\,L^{-1}$, or not at all, with the latter two being classed as impaired awareness [12]. A more complex but well-validated assessment of hypoglycemia burden includes documenting all episodes over a month of observation [69]. Patients with complete hypoglycemia unawareness should be warned against driving and those with incomplete impaired awareness cautioned to use a higher glucose target as indicating safety to drive than those with good awareness, for example $7\,mmol\,L^{-1}$ $(126\,mg\,dL^{-1})$, as blood glucose falls during driving.

Having assessed hypoglycemia risk, the person who is experiencing problems (more than two symptomatic (mild) episodes per week; reduced awareness; recurrent severe episodes) should be investigated. Initial questions depend upon presentation and minor hypoglycemia, or hypoglycemia with an obvious precipitant, may be dealt with by insulin dose adjustment and/or education in insulin dose flexing around, for example, exercise or alcohol intake. A severe hypoglycemic event occurring during a skiing holiday needs a different approach from severe hypoglycemia occurring randomly. Recurring precipitants of hypoglycemic events should be sought by history, assisted by inspection of patient records of glucose monitoring. If nothing in the pattern suggests a remedial regimen error or lifestyle cause, the person should be checked for health issues placing them at particularly high risk (Table 53.1). These are rare but need to be ruled out before focusing exclusively on improving the insulin replacement regimen. Replacement of deficient growth hormone secretion as a treatment for problematic hypoglycemia in an adult with diabetes carries a risk of exacerbating diabetic retinopathy and should only be done cautiously and with regular monitoring of the retinae.

Management of hypoglycemia

Acute episodes

The correct treatment of a hypoglycemia episode is immediate ingestion of a carbohydrate that will rapidly elevate the circulating glucose concentrations. People with insulin-treated

Table 53.2 Assessing individual hypoglycemia exposure

Documentation of experience			
Severe episodes	Requiring assistance	Number since last visit	
		With coma or seizure Requiring admission Requiring emergency services Glucagon given by family/friend	
		Time of day of each	Premeal Post meal Nocturnal
		Possible precipitants	Insulin error Missed meal After increased exercise After increased alcohol Other comorbidity
Mild (symptomatic)	Self-treated	Number per week Times of particular risk	Premeal Post meal
Asymptomatic episodes	Routine SMBG readings <3 mmol L^{-1} with no symptoms	Number per week Times of particular risk	Premeal Post meal
	Others noticing hypoglycemia	Number per week	
		Times of particular risk	Premeal Post meal
Nocturnal episodes		Number per month Possible precipitants	Insulin error Missed meal After increased exercise After increased alcohol Other comorbidity
Other night sweats		Number per month	
Rank ability to feel hypoglycemia by symptoms from 1 (all events) to 7 (never)[a]			
Always aware	1 2 3 4 5 6 7 Never aware		

[a] Gold score, [67].

diabetes should always carry something suitable. Mild episodes can be treated by consumption of 15–20 gm "rapidly available" carbohydrate in the form of 100 mL of non-diet conventional Lucozade, 200 mL fresh fruit juice or, more conveniently for portability, glucose tablets. In the UK, five Bassett's jelly babies currently constitute just over 20 gm— six may be needed with smaller versions. If a meal is not due within the next half hour, a further 20 gm of more slowly absorbed carbohydrate—two semisweet biscuits for example—should also be taken to maintain the glucose concentrations. If a meal is due, the hypoglycemia should be corrected as above, with the usual dose of insulin injected premeal, with a dose reduction if the cause of the original hypoglycemia is still present—for example after exercise. Delaying the meal injection will only drive immediate

postprandial hyperglycemia—the meal carbohydrate content still needs to be managed—and increase the risk of further hypoglycemia later on as the insulin effect continues. Missing the dose altogether predictably results in hyperglycemia. Patients experiencing hypoglycemia sometimes struggle to restrict their carbohydrate intake to the recommended amounts and post-hypoglycemic hyperglycemia may ensue. This should not be corrected with further insulin injection.

Glucose gels are available for buccal administration but if a person is confused, and there are concerns that he/she may not be able to swallow safely, parenteral therapy is recommended. In the home, this can be 1 mg glucagon injected intramuscularly, which will restore circulating glucose concentrations within 10 minutes. Glucagon will not work if hepatic glycogen

stores are depleted, for example within 24 hours of an earlier glucagon-treated hypoglycemia; in liver failure; in cases of severe anorexia or malnutrition, including that associated with long-term severe illness; or if endogenous glucose production is otherwise suppressed, for example in alcohol intoxication. For these reasons, in hospital, intravenous glucose is generally preferred. There is no indication for highly concentrated glucose solutions except in people with acutely compromised circulation and a central line in place. Larger volumes of less concentrated glucose (e.g. 150 mL 10%) are much safer and equally effective. Extravasated 50% glucose can cause local tissue necrosis. Families should not be given responsibility for intravenous therapy. A person with diabetes requiring intravenous glucose needs to be in a properly regulated hospital environment.

After treatment, plasma glucose should be checked within 30 min to ensure recovery. Patients, and healthcare professionals, should be made aware that the risk for a second hypoglycemic event is greatly increased within 24 hours of the first. This is presumably in part because of continuation of the stimulus for the first hypoglycemia, in part because of depletion of glucose stores in liver in the response to the initial hypoglycemia, and in part because of the hypoglycemia-induced impairment of counterregulation described earlier.

Prevention of future events and restoration of impaired hypoglycemia awareness

Having established that a person has problems with hypoglycemia, and that no comorbidity needs treating, the patient's self-management regimen should be checked. Structured education in flexible insulin therapy using multiple daily injections has repeatedly been shown to reduce severe hypoglycemia and even restore impaired awareness, presumably as more physiologic insulin replacement, together with a strategy for adjusting basal as well as meal replacement doses when increasing exercise or alcohol intake, reduces the occurrence of any hypoglycemia [12]. There are many such programs, all teaching people how to assess carbohydrate content of desired food and determine the amount of insulin they require for each unit of carbohydrate based on observation of blood glucose monitoring. They also teach how to adjust basal insulin requirement, to control endogenous glucose production, based on blood tests and lifestyle issues such as activity levels. The UK's Dose Adjustment For Normal Eating (DAFNE) program reports that of the 40% of people coming for training with impaired hypoglycemia awareness, 43% have restored awareness 1 year later. A small number, however, develop impaired awareness apparently *de novo* during the year, leaving 30% with impaired awareness (cf. 40% at entry) at 1 year [12]. This improvement in awareness status is accompanied by a major reduction in severe hypoglycemia rate, associated with significant improvement of glycated hemoglobin, confirming the original observation that such structured education could durably reduce HbA1c and severe hypoglycemia rate at the same time.

Common behaviors that increase hypoglycemia risk that can be addressed in educational programs include failing adequately to reduce insulin active during and/or in the night following exercise or increased alcohol intake; post-meal injection of meal-related insulin; overcorrection of intermittent high blood glucose, for example within 2 hours of eating or on a high but falling glucose following an earlier correction. Fear of modest hyperglycemia may underpin some of these activities.

Some educational packages have been developed specifically targeting avoidance of extremes of blood glucose and concentrate on teaching people techniques to predict their blood glucose (based on a knowledge of their insulin's pharmacodynamics and its interactions with food, exercise, etc.) and better ways of recognizing symptoms of impending hypoglycemia. These have been documented also to reduce hypoglycemia burden [70].

For people who cannot or will not attend such programs, using their principles to reduce hypoglycemia risk is useful, although this has not been formally demonstrated. Ensuring adequate and stable background insulin replacement, for example using twice daily administration of basal insulin, allows flexibility around changes in lifestyle and reduces dependence on meal insulin to provide also insulinization between meals. Taking the evening basal insulin at bedtime, rather than before the evening meal, delays the peak action of the insulin till the time of maximum insulin sensitivity is passed and use of "peakless" basal analogues further diminishes the risk of nocturnal hypoglycemia in patients needing full insulin replacement, as well as providing more stable control of fasting glucose [71]. Use of fast-acting insulin analogues injected 10–15 minutes pre-meal also reduces late hypoglycemic drive, compared to the pre-meal injection of soluble (regular) animal or human insulins, which have a relatively longer duration of action, when between-meal snacking may be required to achieve optimal control. The impact of rapid-acting insulin analogues on nocturnal hypoglycemia suggests that nocturnal hypoglycemia has been driven in part by the tail of the pre-evening meal soluble insulin, which can be offset by bedtime snacking. Flexible insulin therapy training favors adjustment of meal doses according to the amount of carbohydrate the person proposes to eat, and many programs, with careful attention to background as well as meal-related insulin dosing, run without prescribing routine between meal snacking, perhaps because of reduced dependence on the meal insulin to provide basal cover between meals. Routine snacking may become useful in people struggling to achieve good glycemic control because of hypoglycemia before the next meal, assuming the basal contribution has been assessed as appropriate, for example in pregnancy, when there is a need for strict control of pre- *and* postprandial glucose concentrations.

For people whose problems with hypoglycemia persist, replacing multiple daily injection therapy with continuous subcutaneous insulin infusion (CSII), has been shown to achieve a fourfold reduction in severe hypoglycemia risk, in a meta-analysis of studies done mostly in people with clinical indications for pump therapy [72]. It is not known why CSII

has such benefit on severe hypoglycemia rates but its ability to accommodate a dawn phenomenon with reduced nocturnal hypoglycemia may be important, as may the incorporation of devices to assist in bolus calculations that take into account earlier insulin administration. CSII is also associated with improving HbA1c, which should finally break the idea that intensifying insulin therapy and the achievement of optimal glucose control for prevention of structural complication are inextricably linked. "Loosening" diabetes control to deal with hypoglycemia risk simply exchanges one problem for another and the correct management of the person who is hypoglycemia-prone is a reinforcement of the importance of adjusting therapy to stay above the lower limit of the target range.

Early studies of real-time online continuous glucose monitoring excluded people at high risk for hypoglycemia, so event rates were too small to give definitive answers for its ability to prevent hypoglycemia but they may provide benefit [73] especially for those at high risk [74]. A high degree of compliance with sensors may be required for them to provide benefit. A system that allows detection of hypoglycemia by a sensor to drive an automatic suspension of insulin delivery does reduce duration of nocturnal hypoglycemia in those at highest risk and recently has been shown dramatically to reduce severe hypoglycemia in a high-risk group [75]. Closed-loop insulin delivery systems may have more to offer but remain in development at the time of writing.

Transplantation as a treatment for hypoglycemia

For people who cannot stop having severe hypoglycemia despite all of the aforementioned treatments, the option of islet cell replacement by islet cell transplantation is available in some countries. Replacement of functional β cells seems to provide robust protection against severe hypoglycemia in people at very high risk, even if insulin independence is not achieved. The international transplant registry reported that 67% of islet recipients have detectable C-peptide and no hypoglycemia 5 years post transplant, while only 13% of recipients were still insulin independent [76]. Research is developing the techniques involved, from the isolation and manipulation of the islets, to the immunosuppression and anticoagulation used to protect them post transplant and it is expected that these results will improve over time. Whole organ pancreas transplant is another option, discussion of which is beyond the scope of this chapter. Meanwhile, while this treatment is for only a few people worldwide at present, lessons can be learned about how it defends against hypoglycemia, which may be more widely relevant. There are no randomized controlled trials of islet transplantation versus other therapies to reduce hypoglycemia but the people being accepted into islet programs almost all have a long history of hypoglycemia unawareness and high burden of hypoglycemia experience. Possible factors in the success of islet replacement include the replacement of some endogenous insulin which can be suppressed during hypoglycemia and/or a role for C-peptide to have some protective action.

Barriers to avoidance of hypoglycemia and restoration of impaired hypoglycemia awareness

There is evidence to suggest that people with T1DM and impaired hypoglycemia awareness may be less compliant with suggested changes in their self-management regimens than those with preserved awareness. This may relate to abnormal pre-frontal responses to hypoglycemia described previously [45]. In interviews with people experiencing impaired awareness, Rogers found a minority expressed high concern about their condition, with more expressing less concern and less motivation to regain awareness [77], and patients with impaired awareness are less compliant with therapeutic change [78]. It is important to note that a small number of these people did not seem to have a significant clinical problem with hypoglycemia, suggesting that their low level of concern was warranted. The remainder reported less concern despite describing very serious outcomes of experienced hypoglycemia in the past. These people had different cognitions around their hypoglycemia which prevented them engaging in preventive strategies. Among other important issues was the belief that their hypoglycemia could not be prevented, an attitude that may be shared by healthcare professionals. In order to engage people with relatively low concern in strategies to diminish their hypoglycemia, it may be necessary to use techniques specifically directed at motivation and cognitive change [61], although the success of these approaches requires further validation.

Nonhypoglycemic complications of insulin therapy

Weight gain

Weight gain with insulin therapy is a second barrier to achieving good glycemic control and this can be an almost insuperable barrier in some people. People admit to omitting insulin to control weight especially when young. Weight gain may be a particular problem when attempting to improve diabetes control that has been very poor. In that setting, sometimes at diagnosis after weight loss, and sometimes after periods of poor control later in the course of the disease, weight gain is multifactorial [79]. If re-insulinizing after a period of significant insulin deprivation, salt and water retention may result in clinical edema with weight gain. This needs active management and the patient should be encouraged that the effect is transient.

More difficult is the weight gain associated with the retention of calories previously lost in glycosuria. It is claimed that 500 kcals per day can be lost during poor diabetic control through this route. Patients striving to achieve improved glycemic

control need to be aware of this and may be helped by using weight-controlling diets and exercise to offset it. The role of anti-obesity and agents in this context has not been explored.

Other contributors to weight gain with insulin may include a need to eat to prevent or treat hypoglycemia—this should be addressed by revision of the insulin regimen and how the patient is using it. Although in animal studies, insulin in the brain acts to suppress appetite, patients commonly describe insulin as driving them to eat more. It is possible that some insulins have less effect on appetite than others and insulin detemir as a basal insulin in T1DM is associated with reduced food intake and weight gain compared to NPH insulin. This field also requires more investigation.

Weight gain may be associated with other poor health outcomes, such as increased cardiovascular risk. Indeed, as insulin resistance is associated with peripheral hyperinsulinemia and exogenous insulin therapy may also be (see earlier), it has sometimes been suggested that insulin therapy itself may increase cardiovascular risk. An early study of patients in the DCCT showed increased cardiovascular risk in those subjects in the intensive arm who gained most weight. In a long-term follow-up of DCCT participants, significantly less hypertension was found in patients who had received intensive insulin therapy during the DCCT, although it is noted that weight gain in these patients did reduce the effect [80].

Injection site issues

Insulin allergy

Insulin allergy is fortunately rare and commonly directed towards the noninsulin components of insulin preparations. It may present as a local response at the site of injection, with a classical delayed hypersensitivity response, or more rarely manifest as a systemic reaction and occasionally anaphylaxis. Patients can be tried on different insulin formulations but skin testing and blood tests for anti-insulin immunoglobulins should be considered to make a formal diagnosis. Treatment strategies have included use of antihistamine therapies and steroids (both locally in the injection and systemically) and insulin pump therapy, as the continuous exposure to low doses of the allergen appear to induce tolerance. In resistant serious cases, use of immunosuppressive agents to deplete B lymphocytes has been reported [81].

Lipohypertrophy and lipoatrophy

Lipohypertrophy is a local overgrowth of subcutaneous adipose tissue in response to the lipotrophic actions of insulin. It occurs when a patient consistently injects into a site, and is probably very common. The natural tendency is to inject into a site that is routinely available and patients may concentrate on one site as it becomes less sensitive to the sensation of injection. The swelling may be subtle but is poorly vascularized and this may interfere with the efficiency of the injected insulin and/or its

pharmacodynamics. Where carried out to extreme, unsightly swellings can occur and insulin absorption may be significantly affected. Treatment is to avoid further injection into the site and to rotate injection sites thereafter so as not to recreate the problem elsewhere.

Lipoatrophy describes pitting of the skin as the subcutaneous tissue is reduced. It is thought to result from immune complex formation and its occurrence reduced with the introduction of highly purified animal and human insulins, which are less immunogenic than older forms of insulin. It does not seem to have made a reappearance with insulin analogues. Treatment is by "flooding" the affected area with excess antigen, which can be achieved by asking the patient deliberately to inject a purer insulin into the affected site.

Other skin lesions may manifest as a result of poor injection technique. Infection is rare but bleeding, pain, and bruising may require review of technique and sometimes conversion to a different needle length. Usually this will be to a shorter needle, but if insulin leakage is a problem, an 8 mm needle may be better than a shorter one. Intradermal injection can cause small skin lesions, although this may be less of a problem with modern needles.

Fear of injection is multifactorial and in patients with T2DM delaying converting to insulin, reassurance about the natural course of T2DM, and the modern trend to early insulin introduction may help. Some natural anxiety around injections may be resolved after the first self-administration proves not to be painful but cultural issues may complicate patients' acceptance of the need to inject. A true needle phobia should be suspected if the patient describes taking a long time over each injection and injection avoidance. Where suspected, a true needle phobia should be referred for psychiatric assessment and psychologic therapies, although conversion to CSII, as part of the therapy, may help.

Cancer

Certain types of cancer have been associated with insulin resistance and it has been suggested that exogenous insulin therapy may carry similar risk though peripheral hyperinsulinemia. There is no hard evidence to support this claim which is more fully discussed in Chapter 21 [82].

Diabetic ketoacidosis and hyperosmolar state

Abbas E. Kitabchi[1], Guillermo E. Umpierrez[2] and Mary Beth Murphy[1]
[1]The University of Tennessee Health Science Center, Memphis, TN, USA
[2]Emory University School of Medicine, Atlanta, GA, USA

Key points

- Admission for DKA and HHS may be increasing due to economic and psychosocial stressors.
- Mortality rate is higher for HHS than DKA and is characterized by marked stupor without acidosis and extreme elevations of blood glucose with severe dehydration.
- There are three distinct components of DKA: hyperglycemia, acidemia, and ketonemia.
- DKA is classified as mild, moderate, or severe by the American Diabetes Association with options for treatment locations depending on severity.
- Most patients with DKA have autoimmune type 1 diabetes but patients with type 2 diabetes are also at risk for DKA during catabolic stress.
- Hyperglycemic crisis is a pro-inflammatory state with elevations of cardiovascular risk factors, oxidative stress, and pro-inflammatory cytokines which decline after resolution of DKA.
- More than half of obese African Americans with newly diagnosed diabetes presenting with DKA have no apparent precipitating cause. These patients may be labeled idiopathic T1DM, atypical diabetes mellitus, and ketosis-prone T2DM. Interestingly, 40% of these patients remain non-insulin-dependent 10 years after diabetes onset and display a nonautoimmune type of diabetes.
- Common precipitating causes for DKA include: infections, intercurrent illness, psychological stress, and noncompliance with therapy.
- Treatment of DKA includes improvement of organ perfusion by increasing circulatory volume, gradual reduction of osmolarity and glucose, clearance of serum and urine ketones, and normalizing electrolyte levels.
- After recovery of DKA, intravenous infusion of insulin should continue for at least 1 hour while transitioning from intravenous to subcutaneous insulin therapy to prevent regression to DKA.
- Altered sensorium in DKA is independently associated with acidosis.

Introduction

Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS) are the most serious acute metabolic emergencies in type 1 (T1DM) and type 2 diabetes (T2DM). Metabolic derangements result from the combination of absolute or relative insulin deficiency and an increase in counterregulatory hormones (glucagon, catecholamines, cortisol, and growth hormone). Successful treatment of DKA requires frequent monitoring of circulatory volume and tissue perfusion, correction of hypovolemia and hyperglycemia, replacement of electrolyte losses, and a careful search for the precipitating cause. In spite of advances in our understanding of the underlying mechanisms that lead to the development of hyperglycemic crises, DKA continues to be an important cause of morbidity and mortality among patients with diabetes.

The number of hospital admissions for DKA in the US is over 130,000 per year and has shown an upward trend, with a 30% increase in the annual number of cases between 1995 and 2005 [1]. Treatment of DKA utilizes a large number of resources, accounting for an estimated total cost of $2.4 billion annually [1]. In adult patients, recent controlled studies have reported a mortality rate less than 2%, with higher mortality observed in elderly subjects and in patients with concomitant life-threatening illnesses.

This chapter reviews recent advances on the epidemiology, diagnosis, pathogenesis, and current recommendations based on the most recent American Diabetes Association (ADA) guidelines for the management of adult patients with DKA [2].

Diabetic ketoacidosis

Definition and classification

Diabetic ketoacidosis consists of three distinct components: hyperglycemia, acidemia, and ketonemia. Each of these components may be caused by a variety of conditions. According to the recent ADA guidelines, DKA is classified as mild, moderate, or severe based primarily on the blood pH, bicarbonate, ketones, and alteration of sensorium (Table 54.1) [2]. Table 54.1

Table 54.1 Diagnostic criteria and typical total body deficits in DKA and HHS

Diagnostic criteria and classification	DKA			HHS
	Mild	Moderate	Severe	
Plasma glucose, mg dL^{-1}*	>250	>250	>250	>600
Arterial pH	7.25–7.30	7.00<7.24	<7.00	>7.30
Serum bicarbonate, mEq L^{-1}	15–18	10<15	<10	>18
Urine ketone[†]	Positive	Positive	Positive	Small
Serum ketone[†]	Positive	Positive	Positive	Small
Effective serum osmolality[‡]	Variable	Variable	Variable	>320
Anion gap[§]	>10	>12	>12	Variable
Mental status	Alert	Alert/drowsy	Stupor/coma	Variable
Typical deficits	**DKA**			**HHS**
Total water, L	6			9
Water, mL kg^{-1}¶	100			100–200
Na$^+$, mEq kg^{-1}¶	7–10			5–13
CL$^-$, mEq kg^{-1}¶	3–5			5–15
K$^+$, mEq kg^{-1}¶	3–5			4–6
PO4, mmol kg^{-1}¶	5–7			3–7
MG^{++}, mEq kg^{-1}¶	1–2			1–2
CA^{++}, mEq kg^{-1}¶	1–2			1–2

*Euglycemic DKA has been reported [22,23].

†Nitroprusside reaction method.

‡Effective serum osmolality calculation: 2[measured Na$^+$ (mEq L^{-1})] + glucose (mg dL^{-1})/18[mOsm kg^{-1}].

§Anion gap calculation: (Na$^+$)- (CL$^-$ HCO$_3^-$ (mEq L^{-1}) [normal = 12 ± 2].

¶Per kilogram of body weight.

also provides the criteria for the diagnosis of hyperglycemic hyperosmolar state (HHS).

Epidemiology

Observational studies have reported that DKA accounts for 4–9% of hospital discharges among patients admitted with a primary diagnosis of diabetes [3]. A higher figure was reported by the EURODIAB study where 8.6% of 3250 subjects with T1DM throughout Europe had been admitted with DKA in the previous 12 months [4]. Recent epidemiologic studies indicate that hospitalizations for DKA during the past two decades are increasing, with the majority of cases occurring as recurrent cases in the same subjects [1,3].

Most patients with DKA have autoimmune T1DM; however, patients with T2DM are also at risk during the catabolic stress of acute illness such as trauma, surgery, or infection. In contrast to popular belief, DKA is more common in adults than in children. In community-based studies more than 40% of patients with DKA are older than 40 years and more than 20% are older than 55 years [5]. More than half of obese African Americans with newly diagnosed diabetes presenting with DKA have no apparent precipitating cause [6]. At presentation, obese T2 patients with DKA have markedly impaired insulin secretion and insulin action [6]. Intensified diabetic management results in significant improvement in β-cell function and insulin sensitivity sufficient to allow discontinuation of insulin therapy

within a few months of follow-up. This clinical presentation has been reported primarily in African Americans, but also in other minority ethnic groups, and has been labeled idiopathic T1DM, atypical diabetes mellitus, type 1.5 diabetes, and more recently as ketosis-prone T2DM [6,7]. Despite their presentation in DKA, these patients have T2DM because of the presence of obesity, a strong family history of diabetes, measurable insulin secretion, and a low prevalence of autoimmune markers of β-cell destruction [7,8]. Furthermore, 40% remain non-insulin-dependent 10 years after diabetes onset and display a nonautoimmune type of diabetes [9].

In adult subjects with DKA, the overall mortality is less than 1%; however, a mortality rate higher than 5% has been reported in the elderly and in patients with concomitant life-threatening illnesses [2,5]. Death in these conditions is rarely due to the metabolic complications of hyperglycemia or ketoacidosis, but relates to the underlying precipitating illness. The prognosis of both conditions is substantially worsened at the extremes of age, in the presence of coma, hypotension, and severe comorbidities.

Precipitating factors

In patients with known diabetes, precipitating factors for DKA include infections, intercurrent illnesses, psychological stress, and noncompliance with therapy. Worldwide, infection remains the most common underlying cause, occurring in 30–50% of cases [2]. Urinary tract infection and pneumonia account for the majority of infections [10]. Other acute conditions

that may precipitate DKA include cerebrovascular accident, alcohol abuse, pancreatitis, pulmonary embolism, myocardial infarction, surgery, and trauma. Drugs that affect carbohydrate metabolism such as corticosteroids, sympathomimetic agents, and pentamidine may also precipitate DKA. Recently a number of case reports indicate that conventional as well as atypical antipsychotic drugs produce diabetes [11].

In adult patients with T1DM, poor adherence to insulin therapy is reported as the major precipitating cause of DKA in inner city populations [12]. A recent study determined that clinical, socioeconomic, and psychological factors were associated with recurrence of DKA in inner city minority patients [13]. Discontinuation of insulin therapy accounted for over two thirds of all DKA admissions. Several behavioral, socioeconomic, and psychosocial factors contributed to poor treatment adherence. Among patients with poor compliance with insulin therapy, one third of patients "just stopped" insulin with no clear explanation, one third reported financial troubles, and most of the rest reported being away from supply or did not know how to handle insulin on sick days. Other studies have reported that psychological risk factors including eating disorders in up to 20% of recurrent episodes of ketoacidosis in young women [14]. Recently, it was estimated that up to one third of young women with T1DM have eating disturbances [15].

The most common precipitating or predisposing factors for the development of HHS is an infectious process or an intercurrent medical or surgical illness [10,16]. Table 54.2 lists the common predisposing or precipitating factors for the development of HHS.

Pathogenesis

DKA is a state of severe metabolic decompensation characterized by hyperglycemia, metabolic acidosis, and increased total ketone bodies or ketoacids. Ketoacidosis results from insulin deficiency and excess counterregulatory hormones including glucagon, catecholamines, cortisol, and growth hormone. The insulin deficiency of DKA can be absolute in T1DM or relative as in T2DM in the presence of stress or intercurrent illness that causes sudden worsening of insulin resistance and impairment of insulin secretion [16]. In DKA, reduced effective insulin concentrations and increased concentrations of counterregulatory hormones (catecholamines, cortisol, glucagon, and growth hormone) lead to an abnormal metabolism of carbohydrate, protein, and fat as well as disturbances of fluid and electrolyte balances (Figure 54.1). The temporal relationship of the secretion of counterregulatory hormones which leads to the genesis of metabolic decompensation in DKA is the subject of debate. Data on the role of these hormones are based on the results of studies on acute insulin withdrawal in patients with T1DM. Insulin withdrawal in patients with T1DM leads to activation of protein-kinase-induced stimulation of hormone-sensitive lipase in adipose tissue [16]. The increased activity of tissue lipase causes breakdown of triglycerides to glycerol and free fatty acids (FFA). The increased availability of glycerol is utilized as a substrate for gluconeogenesis in

the liver and kidney, whereas the massive release of FFA serves as the main precursor of ketoacids in the liver [17]. Increased production of FFA plays a pivotal role in ketogenesis in DKA [18], by suppressing the glycolytic pathway through the inhibition of the rate-limiting enzymes of glycoloysis (hexokinase, phosphofructokinase, and pyruvate kinase) as well as pyruvate dehydrogenase; increasing production of fatty acyl-CoA, which (a) inhibits the rate-limiting enzyme citrate synthetase, the first step in the TCA (tricarboxylic acid) Krebs cycle, and (b) stimulates hyperlipidemia through conversion to triacylglycerol; and (c) increases β-oxidation of FFA leading to increased ketogenesis (Figure 54.1).

Carbohydrate metabolism

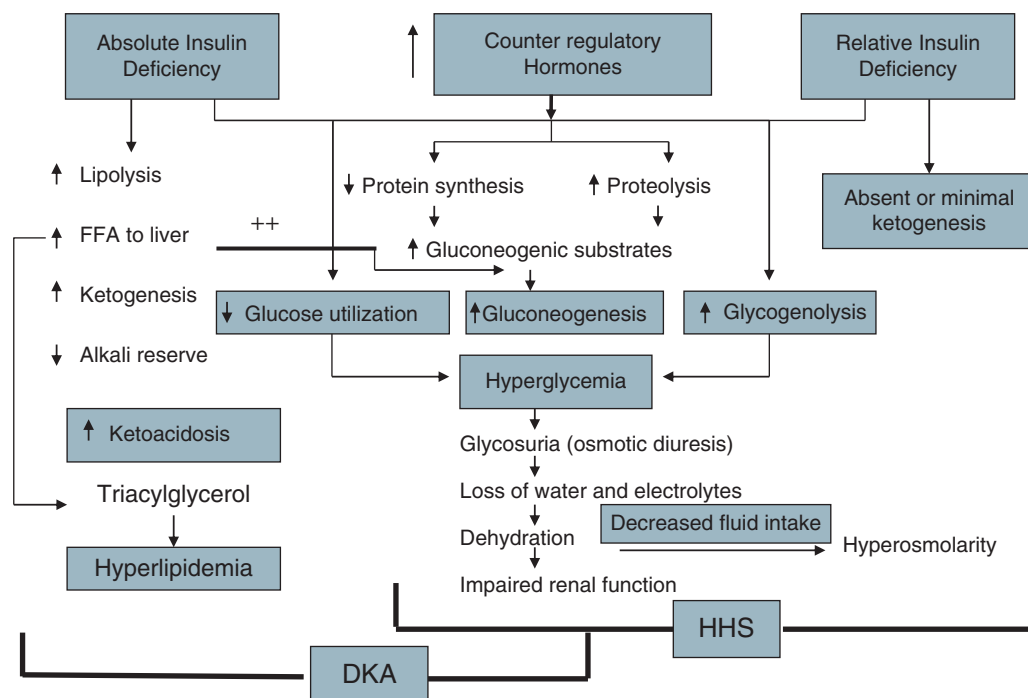
As a result of increased counterregulatory hormones, particularly glucagon and catecholamines, coupled with a reduction of


Figure 54.1 Pathogenesis of DKA and HHS. Source: Kitabchi et al. 2001 [10]. Reproduced with permission of the American Diabetes Association.

insulin, five major pathways of carbohydrate metabolism are affected in DKA [16]:

1 glycogen synthesis is decreased secondary to reduction in glycogen synthase as a result of insulin deficiency;

2 glycogenolysis is accelerated as a result of stimulation of glycogen phosphorylase through catecholamines' β-receptor stimulation and cyclic AMP; glycogen is then broken down to glucose-1-phophosphate;

3 inhibition of glycolysis, as a result of FFA-induced inhibition of rate-limiting glycolytic enzymes (see earlier);

4 decreased glucose utilization by peripheral tissues as a result of insulin deficiency;

5 stimulation of gluconeogenesis by activation of four rate-limiting enzymes: (i) pyruvate carboxylase, (ii) phosphenolpyruvate carboxykinase, (iii) fructose-1,6-biphosphatase, and (iv) glucose-6-phosphatase.

Additionally, increased levels of alanine (in the liver) and glutamine (from the kidney), as a result of increased proteolysis [16,19]; lactate, as a result of decreased glucose oxidation; and glycerol from increased lipolysis serve as substrates for gluconeogenesis. The hepatic glucose production in DKA may be as much as $500\,\mathrm{g\,d^{-1}}$. Although gluconeogenesis occurs mainly in the liver, the kidneys also contribute to this process in patients with DKA [16]. An increased glucagon/insulin ratio also (a) inhibits the level of fructose-2,6-biphophatase leading to a stimulation of fructose-1,6-biphosphatase, (b) stimulates phosphoenolpyruvate carboxykinase, and (c) stimulates glucose-6-phosphatase. The combination of the above pathways leads to hyperglycemia in DKA (Figure 54.1).

Fat and ketone body metabolism

With decreased availability of insulin, the major antilipolytic hormone, and increased counterregulatory hormones such as catecholamines, glucagon, cortisol, and growth hormone, there is an accelerated breakdown of triglycerides to glycerol and FFA through activation of hormone-sensitive lipase [16]. Glycerol, which serves as a carbon skeleton for gluconeogenesis and accelerated production of FFA, leads to its further β-oxidation to ketone bodies. This process is predominantly stimulated by glucagon [17,18]. FFA are also converted to triacylglycerol, which may lead to increased very low density lipoprotein production and hyperlipidemia [18]. In DKA, the combination of increased glucagon and low insulin levels decreases liver malonyl-CoA because of a reduction in hepatic carnitine. Reduced malonyl-CoA will permit activation of the rate-limiting enzyme of ketogenesis, carnitine palmitoyltransferase 1 (CPT-1), which allows transesterification of fatty acyl carnitine and oxidation of FFA to ketone bodies [16,18]. CPT-1 is necessary to move FFA into the mitochondria. In addition, metabolism and clearance of these bodies are decreased in DKA. These biochemical pathways are depicted in Figure 54.1.

Protein and amino acid metabolism

Negative nitrogen balance is the hallmark of DKA [16]. Several studies have shown that severe insulin deficiency results in a loss of 9–12 g of nitrogen per day, with slow recovery after insulin therapy. Furthermore, it was shown that during insulin withdrawal, the levels of gluconeogenic amino acids (glutamine, alanine, threonine, serine, glutamate, and glycine)

were decreased but levels of ketogenic amino acids (such as leucine, valine, and isoleucine) were increased during DKA [16]. It has been suggested that both increased proteolysis and decreased protein synthesis are responsible for these observations, but the detailed mechanism for these steps is not clearly elucidated. However, increased levels of glucagon and cortisol appear to play major synergistic roles.

Water and electrolyte metabolism

Table 54.1 illustrates electrolyte and water deficits in DKA as well as in HHS [10]. The severe derangement of water and electrolytes in DKA and HHS is the result of insulin deficiency, hyperglycemia, and hyperketonemia. Hyperglycemia leads to glucosuria and osmotic diuresis when the renal threshold of glucose ($\sim$200 mg dL^{-1}) is exceeded. The osmotic effects of glucosuria result in impairment of NaCl and water reabsorption in the proximal tubule and loop of Henle, resulting in loss of water, sodium, potassium, as well as other electrolytes [19]. In addition, insulin deficiency per se may also contribute to renal losses of water, sodium, potassium, and ammonium salts because insulin stimulates salt and water reabsorption in the proximal and distal nephron. During the development of DKA, intracellular dehydration also occurs as hyperglycemia and water loss lead to increased plasma tonicity, leading to a shift of water out of cells. This shift of water is also associated with a shift of potassium out of cells into the extracellular space. Potassium shifts are further enhanced by the presence of acidosis and the breakdown of intracellular protein secondary to insulin deficiency. Furthermore, entry of potassium into cells is impaired in the presence of insulinopenia (Figure 54.2) [2].

Increasing evidence indicates that hyperglycemia in patients with DKA is associated with a severe inflammatory state characterized by an elevation of proinflammatory cytokines, reactive oxygen species, and cardiovascular risk factors in the absence of obvious infection or cardiovascular pathology which is improved by the anti-inflammatory effect of insulin and/or the improvement of the stress phenomena brought on by hyperglycemia and hyperlipidemia [20]. Circulating levels of tumor necrosis factor-α, interleukin [IL]-6, IL1-β, and IL-8, C-reactive protein, plasminogen activator inhibitor-1, FFA, cortisol, and growth hormone are significantly increased two- to fourfold on admission in patients with hyperglycemic crises compared with control subjects, and levels returned to normal after insulin treatment and resolution of hyperglycemic crises. Table 54.3 depicts the levels of proinflammatory cytokines, cardiovascular risk factors, counterregulatory hormones, lipid peroxidation and the state of reactive oxygen species in obese and lean patients in hyperglycemic crises at admission and recovery versus obese and lean controls [20].

Diagnosis
History and physical examination
Clinical features of DKA at presentation can be nonspecific but, in general, patients complain of polydypsia and polyuria prior

to the development of DKA. Generalized weakness, weight loss, and gastrointestinal symptoms including nausea, vomiting, and abdominal pain are frequently present on admission [21]. A prospective study of 189 consecutive patients with DKA reported that abdominal pain was present in 46% of patients with DKA and its presence related to the severity of metabolic acidosis and not to the severity of hyperglycemia or dehydration [21]. In DKA subjects with abdominal pain, the mean serum bicarbonate ($9 ± 1$ mmol L^{-1}) and blood pH ($7.12 ± 0.02$) were lower than in patients without pain ($15 ± 1$ mmol L^{-1} and $7.24 ± 0.09$, respectively). Delayed gastric emptying and ileus induced by electrolyte disturbance and metabolic acidosis have also been implicated as possible causes of abdominal pain in DKA [22]. In the majority of patients, the abdominal pain spontaneously resolves after correction of the metabolic disturbance; thus, in the absence of an overt cause for abdominal pain, allowing several hours to treat the underlying acidosis constitutes the best diagnostic tool to elucidate the etiology of abdominal pain in DKA.

Physical examination reveals signs of dehydration, including loss of skin turgor, dry mucous membranes, tachycardia, and hypotension. Most patients are normothermic or even hypothermic at presentation, even in the presence of infections. Acetone on breath and labored Kussmaul respiration may also be present on admission, particularly in patients with severe metabolic acidosis. Mental status can vary from full alertness to profound lethargy; however, fewer than 20% of patients are hospitalized with loss of consciousness [23,24]. Abnormalities in mental status has been found to be independently associated with the level of acidosis as measured by arterial pH as compared to hyperosmolarity or serum "ketone" levels [25]. However, acidosis and hyperosmolarity work in synergy to produce depressed sensorium. Therefore, at presentation, a combination of hyperosmolarity and severe acidosis identifies high-risk adult patients who may benefit from more aggressive therapy and monitoring [25].

Laboratory evaluation

The initial laboratory evaluation should include determination of arterial blood gases, blood glucose, blood urinary nitrogen (BUN), serum electrolytes, creatinine, ketones, osmolality, and urinalysis as well as a complete blood count with differential and bacterial culture for various tissues, as indicated [10]. While waiting for the laboratory tests, an initial blood glucose test by finger stick as well as a dipstick urinalysis for glucose, ketone, nitrite, and leukocyte esterase can give the clinician an insight into the severity and precipitating factors leading to metabolic decompensation. Because of the rather restrictive criteria for the diagnosis of DKA in the past, the recent ADA guidelines have provided three classification levels of DKA to outline different approaches to therapy, depending on the degree of ketoacidosis (Table 54.1).

The plasma anion gap, which is not a criterion for diagnosis, is calculated by subtracting the major measured anions (chloride and bicarbonate) from the major measured cation (sodium). The normal anion gap has been historically reported to be $12 ± 2$ mEq L^{-1} [2]. Although most subjects with DKA present with a high anion gap acidosis, some patients present with mixed acid–base disorders [26]. It has been reported that 46% of patients admitted with DKA had predominant anion gap acidosis, 43% had mixed anion gap acidosis and hyperchloremic metabolic acidosis, and 11% had hyperchloremic metabolic acidosis [24]. During treatment, a transient hyperchloremic normal anion gap metabolic acidosis has been reported in the majority of patients [10].

Effective osmolality can be calculated by the following formula: 2[measured Na+ (mEq L^{-1})] + glucose (mg dL^{-1})/18. The sodium concentration in DKA is not adjusted to the glucose concentration for calculation of osmolality. However, the sodium concentration should be adjusted by glucose concentration for clinical treatment decisions when assessing actual serum sodium concentration. Table 54.4 outlines the laboratory evaluation of metabolic causes of acidosis and coma [10].

Laboratory pitfalls

Clinical assessment of ketonuria and ketonemia has traditionally been done by the use of the nitroprusside tablet or Ketostix, which only reacts with acetoacetate and acetone [10,27] and fails to detect β-hydroxybutyrate, the most important ketone body in patients with DKA. During therapy, β-hydroxybutyrate is converted to acetoacetate, so measurement of acetoacetate by the nitroprusside test as an indication of DKA recovery, may be misleading. The recent availability of self-glucose monitoring systems, which also contain a mechanism for measurement of β-hydroxybutyrate by finger stick, has led to a marked improvement in the management of patients with DKA [2,27,28].

Leukocytosis, which is common in patients with DKA, may not be indicative of an infectious process, particularly when total white blood cell counts are below 25,000 [29]. The reason for this elevation has not been established. The majority of white cells in leukocystosis are granulocytes with no detectable eosinophil counts (as a result of hypercortisolism) [29]. Leukocytosis (total white blood cell counts >25,000) requires further assessment for an underlying infection. The admission serum sodium is usually low because of the osmotic flux of water from the intracellular to the extracellular space in the presence of hyperglycemia. An increase in serum sodium concentration in the presence of hyperglycemia indicates a rather profound degree of water loss. To assess the severity of sodium and water deficit, serum sodium may be corrected by adding 1.6 mg dL^{-1} to the measured serum sodium for each 100 mg dL^{-1} of glucose above 100 mg dL^{-1}. Extreme hypertriglyceridemia, which may be present during the DKA may cause lipemic serum with spurious lowering of serum sodium (pseudohyponatremia) [16]. Serum potassium is commonly elevated as a result of cellular dehydration and shift of potassium from the intracellular to the extracellular space [30], and to the breakdown of intracellular protein secondary to insulin deficiency.

Other laboratory abnormalities in patients with DKA include hyperamylasemia, which has been reported in 21–79% of cases [31]. There is little correlation between the presence, degree, or isoenzyme type of hyperamylasemia and the presence of gastrointestinal symptoms, triglyceride concentration, or pancreatic imaging studies. The cause of hyperamylasemia in DKA is postulated to be multifactorial; the most important causes include the existence of salivary amylase, reduced renal clearance of amylase, and increased leakage from acinar cells secondary to neural and metabolic disturbances. Nonspecific

serum lipase elevation has also been noted in 29–41% of patients with DKA in the absence of clinical or radiologic evidence of acute pancreatitis.

Recent studies have shown decreased serum leptin in obese and thin patients with DKA as well as obese hyperglycemic patients. These levels normalize after correction of hyperglycemia [32]. Furthermore, recent studies on proinflammatory factors in hyperglycemic crises demonstrate significant increases in TNF-α, IL-1, IL-6, and IL-8 [20]. These increased cytokines are also associated with *de novo* emergence of growth factor in activated T-lymphocytes for insulin, IGF-1, and IL-2 [33].

Hyperglycemic hyperosmolar state

Definition

Hyperglycemic hyperosmolar syndrome (HHS) was first described by Dreschfeld [32] over a century ago, but this condition received little attention until 1957, when Sament and Schwartz [34] reported their experience of a diabetic syndrome characterized by marked stupor without ketosis (diabetic hyperosmolar syndrome). HHS is characterized by extreme elevations in serum glucose concentrations and hyperosmolality without significant ketosis may occur in patients with T1 and T2DM. Criteria for the diagnosis of HHS include a serum glucose concentration >600 mg dL^{-1} (33 mmol L^{-1}), a serum osmolality >330 mOsm kg^{-1}, and lack of significant ketosis and acidosis (serum bicarbonate >5 mmol L^{-1}, serum pH >7.30) [2]. Overlap between HHS and DKA may occur, and some patients with HHS—especially when there is severe dehydration—experience mild or moderate acidosis (Table 54.1). Altered sensorium (lethargy, stupor, and coma) is common and correlates better with hyperosmolality than with patient's age or severity of acid–base disturbance. Several reports have shown that the mean total serum osmolality in patients who presented in coma is greater than 340 mmol kg^{-1} [35,36].

Epidemiology

Although epidemiologic reports on HHS are sparse, data collected from 1979 to 1981 by an NIH data group suggest an incidence of 10 cases per 100,000 of the general population [1]. This is about one sixth that of DKA. More recently, the incidence of HHS in two different teaching institutions in the United States was 0.05% of all diabetes-related admissions [37]. Mortality attributed to HHS is considerably higher than with DKA, with recent mortality rates of 5–35%, most likely depending on the underlying illness or comorbidities [35].

Precipitating and predisposing factors

In general, subjects with HHS have a history of symptoms of hyperglycemia for several days and patients present to the emergency room with an altered mental status [38]. The typical patient with HHS is between 55 and 70 years old and frequently

Table 54.4 Laboratory evaluation of metabolic causes of acidosis and coma

	Starvation or high fat intake	DKA	Lactic Acid	Uremic acidosis	Alcholic ketosis (starvation)	Salicylate Intoxication	Methanol or ethylene glycol intoxication	Hypersmolar coma	Hypoglcemic coma	Rhabdomyolysis

is a nursing home resident or someone who has delayed seeking medical attention [36,38]. Infection is the major precipitating factor occurring in 30–60% of patients, with urinary tract infections and pneumonia being the most common infections [36,38,39].

HHS is the initial manifestation of diabetes in 7–17% of patients [36–39]. Other precipitating causes of HHS include an acute illness, such as cerebrovascular accident or myocardial infarction that provokes the release of counterregulatory hormones and/or compromises access to water [36–39]. Certain medications that cause DKA may also precipitate the development of HHS, including glucocorticoid, thiazide diuretics, dilantin, and β-blockers. See Table 54.2 for predisposing or precipitating factors for HHS.

Pathogenesis

The underlying pathogenic mechanism for HHS is a reduction in the net effective concentration of circulating insulin and a concomitant elevation of counterregulatory or stress hormones such as glucagon, catecholamines, cortisol, and growth hormone in association with severe dehydration [35,36]. DKA and HHS represent opposite ends of the spectrum of hyperglycemia with and without ketosis, respectively (Figure 54.2). However, mixed mild ketotic hyperosmolar conditions may exist, with about one third of DKA patients having features of HHS [40].

Several mechanisms have been proposed to explain the absence or minimal presence of ketosis in patients with HHS. Key differences between DKA and HHS include: (a) higher levels of endogenous insulin reserve in HHS (i.e., adequate insulin concentration to prevent lipolysis but inadequate to inhibit hepatic glucose production and/or stimulate glucose use); (b) lower levels of counterregulatory hormones and FFA in HHS; and (c) inhibition of lipolysis by the hyperosmolar state, thereby decreasing ketogenesis. Early studies comparing 12 cases of HHS and 22 cases of DKA confirmed a higher level of growth hormone, but revealed no significant difference in either FFA or cortisol in the two groups (Table 54.5) [41]. Although earlier studies were not able to demonstrate differences in pancreatic insulin secretion between patients with HHS and DKA, it is important to note that prior to 1980, the measurement of insulin was not specific and could not separate proinsulin from insulin and a standardized C-peptide assay was not used. More recent studies [20] have demonstrated a higher level of C-peptide in HHS than in DKA [20]. Similar results were observed recently in lean African-American patients with DKA as compared to obese DKA and obese nonketotic hyperglycemia state (Table 54.6) [20]. Therefore, the most likely reason for the lack of ketoacidosis in HHS appears to be a higher level of pancreatic insulin reserve than in DKA. This is due to the fact that the antilipolytic effect of insulin is about one tenth of that of glucose utilization [10]. Another potential mechanism for the lack of ketosis in HHS involves the effect of hyperosmolality on inhibiting lipolysis, insulin secretion, and glucose uptake. Hepatic glucose production in HHS is

higher than that in DKA and may be as high as 1 kg per day. Equally important is the glomerular filtration rate, which may be decreased with increasing age, exacerbating the level of hyperglycemia, decreasing intravascular space, and leading to tachycardia and hypotension.

Diagnosis

As shown in Table 54.1, the diagnosis of HHS is characterized by a higher level of glucose levels, absence of metabolic acidosis, minimal or negative ketosis, and higher serum osmolality [10]. These patients are obtunded more often than DKA patients. Furthermore, biochemical data on admission suggest slightly higher sodium, BUN, creatinine, osmolality, and possibly higher serum lactate levels than in DKA (Table 54.5) [41].

The typical patient with HHS has undiagnosed diabetes, is between 55 and 70 years of age, and frequently is a nursing home resident. Most patients who develop HHS do so over days to weeks during which they experience polyuria, polydipsia, and progressive decline in the level of consciousness. The most common clinical presentation for patients with HHS is altered sensorium [39]. Physical examination reveals signs of volume depletion. Fever due to underlying infection is common, and signs of acidosis (Kussmaul respiration, acetone breath) are usually absent. Gastrointestinal manifestations (abdominal pain, vomiting) frequently reported in patients with DKA are not part of HHS, thus the presence of abdominal pain in patients without significant metabolic acidosis needs to be investigated. In some patients, focal neurologic signs (hemiparesis, hemianopsia) and seizures (partial motor seizures more common than generalized) may be the dominant clinical features, resulting in a common misdiagnosis of stroke [39].

Despite the focal nature of neurologic findings, the neurologic manifestations often reverse completely after correction of metabolic disorder.

The diagnostic criteria for HHS include a plasma glucose concentration greater than $600 \, \text{mg} \, \text{dL}^{-1}$, a serum osmolality greater than $320 \, \text{mOsm} \, \text{kg}^{-1}$ of water, and the absence of significant ketoacidosis. Although by definition, patients with HHS have a serum pH greater than 7.3, a serum bicarbonate greater than $18 \, \text{mEq} \, \text{L}^{-1}$, and negative ketone bodies in urine and plasma, mild ketonemia may be present. Approximately 50% of the patients with HHS have an increased anion gap metabolic acidosis as the result of concomitant ketoacidosis and/or to an increase in serum lactate levels [5].

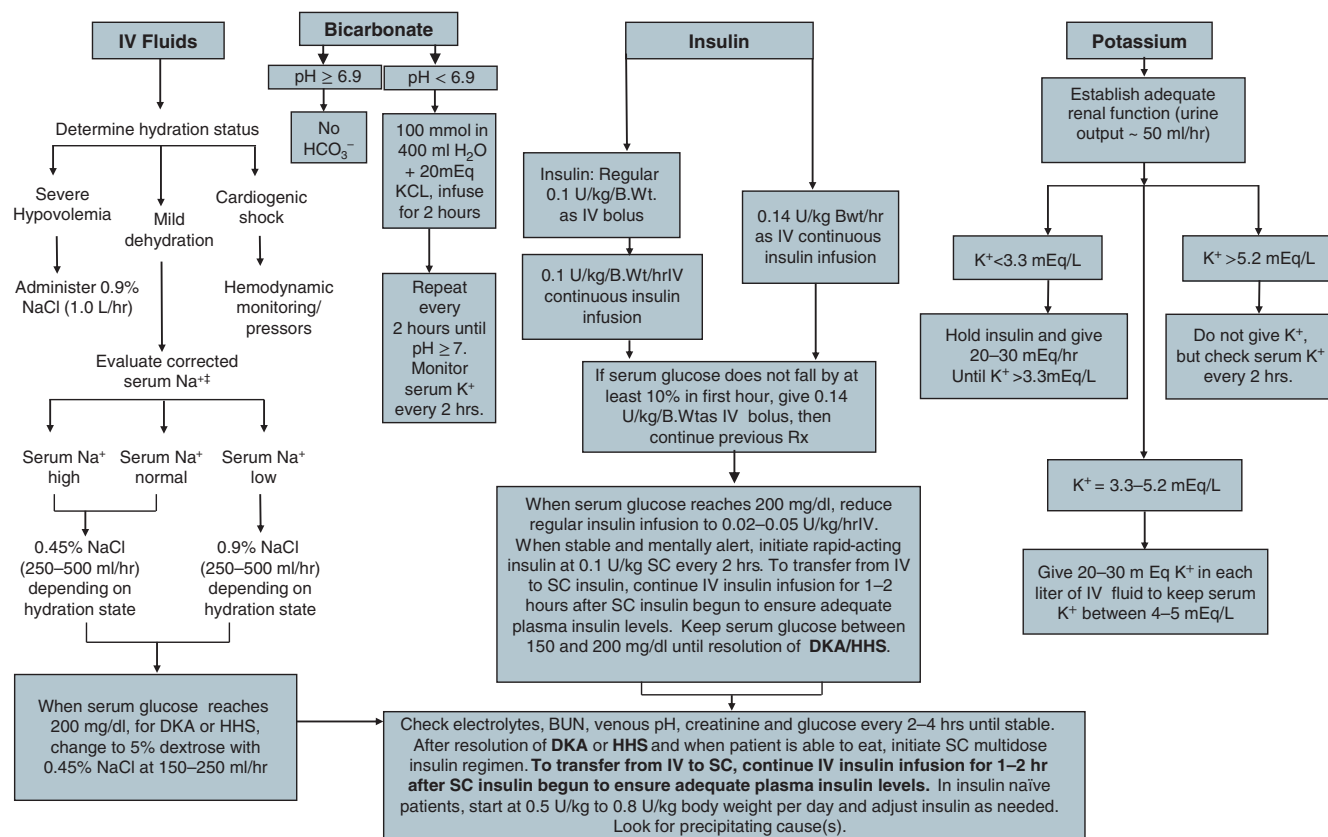
Treatment of hyperglycemic crises

Because DKA and HHS have essentially the same underlying pathogenesis consisting of insufficient insulin and loss of fluid and electrolytes, the major therapeutic goals include: (a) improvement of organ perfusion by increasing circulatory volume, (b) gradual reduction of osmolality, (c) gradual correction of serum glucose, (d) clearance of both serum and urine of ketones, and (e) normalization of electrolyte levels [2,16]. Careful and frequent monitoring of these patients every 30–60 min for the first 4 hours and subsequently every hour is the most important aspect of management of patients with hyperglycemic crises. Figure 54.3 summarizes the algorithm for the treatment of DKA and HHS [42].

Hydration and fluid therapy

As reported by previous investigators, hydration alone has been shown to increase extra cellular volume, lower serum glucose, decrease hyperosmolality, reduce circulating levels of counterregulatory hormones, and improve insulin resistance [43]. Because of severe loss of intravascular volume and electrolytes in both DKA and HHS, the initial fluid therapy should be one liter of isotonic saline, which will expand extracellular fluid and restore renal perfusion. The rate of isotonic solution should be given at $15–20 \, \text{mL} \, \text{kg}^{-1} \, \text{h}^{-1}$. The tonicity and volume of subsequent sodium chloride solutions should be determined by the state of hydration and by the corrected serum sodium value (Figure 54.3). In general, 0.45% sodium chloride solution after the initial normal saline will expand intracellular and interstitial space volume and normalize the contracted volume within a few hours, and should continue until blood glucose reaches $200 \, \text{mg} \, \text{dL}^{-1}$ in DKA or HHS. At this time, the hydrating fluid should be changed to 5–10% glucose-containing saline with a concomitant reduction of i.v. insulin to $0.02–0.05 \, \text{U} \, \text{kg}^{-1} \, \text{h}^{-1}$. Plasma glucose levels should remain $\sim 200 \, \text{mg} \, \text{dL}^{-1}$ until bicarbonate and pH reach normal levels in DKA and serum osmolality and mental status in patients with HHS is normalized. An additional important aspect of fluid management in hyperglycemic states is to replace the volume of urinary losses. Failure to adjust fluid replacement for urinary losses may delay correction of electrolytes and water deficit [10].

Insulin therapy

The cornerstone of DKA and HHS management is insulin therapy. Insulin increases peripheral glucose utilization and decreases hepatic glucose production, thereby lowering blood glucose concentration. In addition, insulin therapy inhibits the release of FFA from adipose tissue and decreases ketogenesis, both of which lead to the reversal of ketogenesis. In critically ill and mentally obtunded patients, regular insulin given intravenously by continuous infusion is the treatment of choice. Such patients should be admitted to an intensive care unit or to a step-down unit where adequate nursing care and quick


*DKA diagnostic criteria: blood glucose 250 mg/dl, arterial pH 7.3, bicarbonate 15, mEq/l, and moderate ketonuria or ketonemia
†15–20 ml/kg/h
‡ Serum Na should be corrected for hyperglycemia (for each 100 mg/dl glucose 100 mg/dl, add 1.6 mEq to sodium value for corrected serum value)

Figure 54.3 Protocol for management of adult patients with DKA or HHS.* Initial evaluation: After history and physical examination, obtain arterial blood gases, complete blood count with differential, urinalysis, plasma glucose, BUN, electrolytes, chemistry profile, and creatinine levels immediately, as well as ECG. Chest radiography and cultures as needed. Start i.v. fluids: 1.0 L of 0.9% NaCl per hour.†

turnaround of laboratory tests results are available. As shown in Figure 54.3, the i.v. insulin protocol includes a continuous infusion of regular insulin at a dose of $0.14 \, \text{U} \, \text{kg}^{-1} \, \text{h}^{-1}$ ($5\text{–}10 \, \text{U} \, \text{h}^{-1}$) or an initial i.v. bolus of regular insulin of $0.1 \, \text{U} \, \text{kg}^{-1}$ of body weight, followed by a continuous infusion of regular insulin at a dose of $0.1 \, \text{U} \, \text{kg}^{-1} \, \text{h}^{-1}$ ($5\text{–}10 \, \text{U} \, \text{h}^{-1}$) should be administered. This will result in a fairly predictable decrease in plasma glucose concentration at a rate of $65\text{–}125 \, \text{mg} \, \text{h}^{-1}$ [42]. When plasma glucose levels reaches $\sim200 \, \text{mg} \, \text{dL}^{-1}$, the insulin infusion rate is reduced to $0.02\text{–}0.05 \, \text{U} \, \text{kg}^{-1} \, \text{h}^{-1}$ ($3\text{–}5 \, \text{U} \, \text{h}^{-1}$), and dextrose ($5\text{–}10\%$) should be added to i.v. fluids. Thereafter, the rate of insulin administration may need to be adjusted to maintain the above glucose values until ketoacidosis or mental obtundation and hyperosmolality are resolved. During therapy, capillary blood glucose should be determined every $1\text{–}2$ hours at the bedside using a glucose oxidase reagent strip; and blood should be drawn every $2\text{–}4$ hours for determination of serum electrolytes, glucose, blood urea nitrogen, creatinine, magnesium, phosphorus, and venous pH.

A conscious patient with mild DKA could be treated with subcutaneous (s.c.) or intramuscular (i.m.) insulin in a general hospital ward. In such patients, the administration of regular insulin every $1\text{–}2$ hours by the s.c. or i.m. route has been shown to be as effective in lowering blood glucose and ketone bodies concentration as giving the entire insulin dose by i.v. infusion without addition of albumin [38,39]. Blood insulin levels using the i.m. and s.c. route may take $1\text{–}2$ hours before reaching postprandial physiologic levels ($70\text{–}100 \, \mu\text{U} \, \text{mL}^{-1}$), whereas i.v. insulin reaches supraphysiologic insulin level in a few minutes. The use of i.v. and s.c. (or i.m.) insulin is an acceptable therapeutic approach in a non-ICU setting [39,40]. Recent prospective randomized studies comparing the use of rapid-acting insulin (lispro) s.c. route versus i.v. infusion in the ICU, in mild to moderate DKA patients, has been reported to be as effective as a standard i.v. low-dose regular insulin protocol. In these studies, the mean time of insulin treatment to correct hyperglycemia and ketoacidosis was similar between s.c. lispro and i.v. infusion of regular insulin [37].

Transition to subcutaneous insulin

Patients with DKA should be treated with continuous i.v. insulin until ketoacidosis is resolved. Criteria for resolution of ketoacidosis include: a blood glucose lower than $200 \, \text{mg} \, \text{dL}^{-1}$, a serum bicarbonate level equal to or greater than $18 \, \text{mEq} \, \text{L}^{-1}$, a venous pH greater than 7.3, and a calculated anion gap equal to or lower than $14 \, \text{mEq} \, \text{L}^{-1}$ [2]. Serial measurements of point-of-care capillary blood β-hydroxybutyrate (β-OHB) concentrations have been proposed to monitor biochemical resolution of DKA and to determine when i.v. insulin infusion should be stopped. Blood β-OHB levels decrease to $<1 \, \text{mmol} \, \text{L}^{-1}$ many hours before the urine becomes ketone-free [44]. Absence of ketonuria should not be used as an endpoint for determining resolution of DKA.

The American Diabetes Association (ADA) position statement recommends the transition to a split-mixed insulin regimen with neutral protamine Hagedorn (NPH) and regular insulin twice daily or to a multidose regimen of short- or rapid-acting and intermediate- or long-acting insulin [2]. Several studies have reported hospital rates of hypoglycemic events up to 30% with the use of NPH and regular insulin after discontinuation of i.v. insulin [45]. The inadequate duration of action of NPH insulin and an undesirable peak activity at $4\text{–}6$ hours after injection [45] as well as the high day-to-day variability in absorption [45] partially explain the high rate of hypoglycemic events. A recent randomized study compared the safety and efficacy of insulin analogues and human insulin during the transition from i.v. to s.c. insulin in patients with DKA. During the transition to s.c. insulin, there were no differences in mean daily glucose levels, but 41% patients treated with NPH/regular had a higher rate of hypoglycemia compared to 15% of patients treated with glargine once daily and glulisine before meals [45]. Thus, a basal/bolus regimen with insulin analogues is safer and should be preferred over NPH and regular insulin following the resolution of DKA. To prevent recurrence of hyperglycemia and/or ketoacidosis during the transition period to s.c. insulin, it is important to allow an overlap of $1\text{–}2$ hours between discontinuation of i.v. insulin and the administration of s.c. insulin [45].

The most convenient time to change to s.c. insulin is in the morning or evening. For patients previously on a basal-bolus insulin regimen, the first s.c. injection of rapid-acting insulin should be given 15 min prior to the meal depending on the plasma glucose concentration. This method allows sufficient time for the injected insulin to be absorbed. Then the first basal injection is given and the insulin infusion is stopped 1 hour later.

In patients with established diabetes, the patient's usual insulin regimen may be resumed. In adult patients with newly diagnosed diabetes, an initial insulin total insulin dose of $0.5\text{–}0.8 \, \text{U} \, \text{kg}^{-1} \, \text{d}^{-1}$ is usually sufficient to achieve and maintain metabolic control [2,37]. After transitioning to s.c. insulin, frequent blood glucose monitoring is required to avoid marked hyperglycemia and hypoglycemia. Supplemental rapid-acting insulin is given before meals or at $4\text{–}6$-hour intervals to correct hyperglycemia.

Potassium

Despite a total body potassium deficit of $\sim3\text{–}5 \, \text{mEq} \, \text{kg}^{-1}$ of body weight, most patients with DKA have a serum potassium level at or above the upper limits of normal [46]. These high levels occur because of a shift of potassium from the intracellular to the extracellular space due to acidemia, insulin deficiency, and hypertonicity. Both insulin therapy and correction of acidosis decrease serum potassium levels by stimulating cellular potassium uptake in peripheral tissues. Therefore to prevent hypokalemia, most patients require i.v. potassium during the course of DKA therapy. Replacement with i.v. potassium should

be initiated as soon as the serum potassium concentration is below 5.5 mEq L^{-1}. The treatment goal is to maintain serum potassium levels within the normal range of 4 to 5 mEq L^{-1}. In some hyperglycemic patients with severe potassium deficiency, insulin administration may precipitate profound hypokalemia [46], which can induce life-threatening arrhythmias and respiratory muscle weakness. Thus, if the initial serum potassium is lower than 3.3 mEq L^{-1}, potassium replacement should begin immediately by an infusion of potassium chloride at a rate of 20–30 mEq h^{-1}, and insulin therapy should be delayed in patients with significant hypokalemia (Figure 54.3).

Bicarbonate

Most current ADA guidelines [2] do not recommend the routine use of alkali therapy in DKA because bicarbonate levels tend to correct with insulin therapy. Insulin administration inhibits ongoing lipolysis and ketoacid production and promotes ketoanion metabolism. Because protons are consumed during ketoanion metabolism, bicarbonate is regenerated, leading to partial correction of metabolic acidosis. The use of bicarbonate in HHS is not recommended, as patients exhibit normal serum bicarbonate, unless there is a condition of mixed hyperosmolar ketoacidosis. The use of bicarbonate in DKA, however, may be used in patients with either severe bicarbonate deficiency (below 5 mM) or severe acidemia (pH less than 6.9). However, the use of bicarbonate in DKA at this level of acidosis is controversial because of the potential deleterious effects of bicarbonate including paradoxical central spine fluid (CSF) acidosis, rebound alkalosis, hypokalemia, and increased lactate production as well as local irritation with bicarbonate administration. The theoretical advantage of bicarbonate therapy may be due to its salutary effect on advanced acidosis and improvement of the negative ionotropic effect on the heart and peripheral vasodilatation [47]. Several prospective and retrospective studies have demonstrated conflicting results regarding the use of bicarbonate therapy in DKA. Two studies have shown increases in blood pH when bicarbonate therapy was compared to saline infusion [47]. There are no large studies to demonstrate the efficacy of bicarbonate therapy in patients with DKA and pH less than 6.9. In the absence of such data, the ADA guidelines recommend that patients with pH lower than 6.9 should receive two ampules of bicarbonate (100 mmol) as an isotonic solution (in 400 mL of water) at the rate of 50 mmol h^{-1} with 20 mEq of KCL [2]. For follow-up of acidosis, we recommend measuring venous rather than arterial pH every 2 hours, realizing that venous pH is approximately 0.03 lower than the arterial pH.

Phosphate

Total body phosphate deficiency is universally present in patients with DKA, but its clinical relevance and benefits of replacement therapy remain uncertain. Several studies have failed to show any beneficial effect of phosphate replacement on clinical outcome [48]. Furthermore, aggressive phosphate therapy is potentially hazardous, as indicated in case reports of children with DKA who developed hypocalcemia and tetany secondary to i.v. phosphate administration [48]. Theoretic advantages of phosphate therapy include prevention of respiratory depression and generation of erythrocyte 2,3-diphosphoglycerate. Because of these potential benefits, careful phosphate replacement may be indicated in patients with cardiac dysfunction, anemia, respiratory depression, and in those with serum phosphate concentration lower than 1.0–1.5 mg dL^{-1} [48]. If phosphate replacement is needed, it should be administered as a potassium salt, by giving half of the potassium replacement as potassium phosphate and half as potassium chloride. In such patients, because of the risk of hypocalcemia, serum calcium and phosphate levels must be monitored during phosphate infusion.

Management of patients after resolution of hyperglycemic crisis

Patients with moderate to severe DKA should be treated with continuous i.v. insulin until ketoacidosis is resolved. Criteria for resolution of ketoacidosis include a blood glucose lower than 200 mg dL^{-1}, a serum bicarbonate level equal to or greater than 18 mEq L^{-1}, a venous pH greater than 7.3, and a calculated anion gap equal to or lower than 12 mEq L^{-1}. The criteria for resolution of HHS include improvement of mental status, blood glucose <200 mg dL^{-1}, and a serum osmolality of less than 320 mOsm kg^{-1}. When this occurs, s.c. insulin therapy can be started. If the patient is able to eat, split-dose therapy with both rapid/short-acting insulin and basal insulin may be given. It is easier to make this transition in the morning—before breakfast—or at dinnertime. Patients with known diabetes may be given insulin at the dosage they were receiving before the onset of DKA. In patients with newly diagnosed diabetes, an initial insulin total insulin dose of 0.5–0.8 U kg^{-1} d^{-1} is usually sufficient to achieve and maintain metabolic control. Two thirds of this total daily dose should be given in the morning and one third in the evening as a split-mixed dose. If the patient is not able to eat, continue the i.v. insulin infusion protocol. However, the patient could receive s.c. regular insulin every 4 hours while an infusion of 5% dextrose in half-normal saline is given at a rate of 100–200 mL h^{-1}. A critical element is to avoid recurrence of hyperglycemia or ketoacidosis during the transition period to s.c. insulin by allowing an overlap of i.v. insulin for 1–2 hours during the initiation of s.c. regular insulin to insure adequate plasma insulin levels.

Figure 54.3 illustrates step-by-step guidelines for management of patients with DKA and HHS approved by the ADA. It is important to point out, however, that no set of guidelines can replace individualized management of the patient in DKA or HHS.

Complications of therapy

The most common complications of DKA treatment are hypoglycemia and hypokalemia. Despite the use of low-dose insulin protocols, hypoglycemia is still reported in 10–25% of patients with DKA [2,37,49]. The failure to reduce insulin infusion rate and/or to use dextrose-containing solutions when blood glucose levels reaches $250\,mg\,dL^{-1}$ are the most important risk factors associated with hypoglycemia during insulin infusion. Frequent blood glucose monitoring (every 1–2 hours) is mandatory to recognize hypoglycemia and serious complications. Many patients with hyperglycemic crises who experience hypoglycemia during treatment do not experience adrenergic manifestations of sweating, nervousness, fatigue, hunger, and tachycardia despite low blood glucose levels. Clinicians should be aware that recurrent episodes of hypoglycemia may be associated with a state of hypoglycemia unawareness (loss of perception of warning symptoms of developing hypoglycemia), which may complicate diabetes management after resolution of hyperglycemic crises. Hypoglycemia is not a major problem in patients with HHS. Glucose values lower than $60\,mg\,dL^{-1}$ have been reported in less than 5% of HHS patients during i.v. insulin therapy [2,37].

Although the admission serum potassium concentration is commonly elevated in patients with DKA and HHS, plasma concentration of potassium will invariably decrease as a result of treatment. Both insulin therapy and correction of acidosis decrease serum potassium levels by stimulating cellular potassium uptake in peripheral tissues. Thus, to prevent hypokalemia, replacement with i.v. potassium should be initiated when the serum potassium concentration is below $5.5\,mEq\,L^{-1}$. In patients admitted with normal or reduced serum potassium, insulin administration may precipitate profound hypokalemia. Thus, if the initial serum potassium is less than $3.3\,mEq\,L^{-1}$, i.v. potassium replacement should begin immediately and insulin therapy should be held until serum potassium reaches $3.3\,mEq\,L^{-1}$ (see Figure 54.3).

Cerebral edema is a rare but serious complication of DKA, occurring in approximately 1% of episodes of diabetic ketoacidosis in children [44,45], and is associated with a mortality rate of 40–90% [50]. Clinically cerebral edema is characterized by decreasing level of consciousness and headache, followed by seizures, sphincter incontinence, pupillary changes, papilledema, bradycardia, and respiratory arrest. It has been hypothesized that cerebral edema in children with diabetic ketoacidosis may be caused by the rapid shift in extracellular and intracellular fluids and changes in osmolality due to accumulation of osmolytes in brain cells exposed to hyperosmolar conditions [50]. A rapid decrease in extracellular osmolality during treatment would then result in osmotically mediated swelling of the brain. Although osmotic factors and other mechanisms may play a part in the development of cerebral edema, recent data suggest that cerebral edema in children with diabetic ketoacidosis is related to brain ischemia [50]. In children with diabetic ketoacidosis, both hypocapnia (which causes cerebral vasoconstriction) and extreme dehydration (as determined by a high initial serum urea nitrogen concentration) were associated with increased risk for cerebral edema. Hyperglycemia superimposed on an ischemic insult increases the extent of neurologic damage, blood–brain barrier dysfunction, and edema formation.

In addition, it has been shown that an inadequate correction in serum sodium concentration during therapy may be associated with increased risk of cerebral edema [50]. The more frequent occurrence of cerebral edema in children than in adults may be explained in part by the fact that children's brains have higher oxygen requirements than adults' brains and are thus more susceptible to ischemia. Measures that may decrease the risk of cerebral edema in high-risk patients are gradual replacement of sodium and water deficits in patients with high serum osmolality (maximal reduction in osmolality $3\,mOsm\,kg^{-1}\,h^{-1}$) and the addition of dextrose to the hydrating solutions once blood glucose reaches $250\,mg\,dL^{-1}$ in DKA and $300\,mg\,dL^{-1}$ in HHS [10]. Patients with cerebral edema should be transferred to an intensive care unit setting. If signs of increased intracranial pressure or brain herniation are present, only 7–14% of patients recover without permanent significant neurologic disabilities. Treatment includes the immediate use of i.v. mannitol [10], reduction of fluid administration rate, and possible mechanical ventilation to help reduce brain swelling [10]. Corticosteroid and diuretic therapy are of no proven benefit in the immediate use of i.v. mannitol [10].

Prevention of hyperglycemic crises

One of the major precipitating factors in both DKA and HHS is inadequate insulin dosing or omission of insulin injection. The frequency of hospitalizations for DKA has been reduced following diabetes education programs, improved follow-up care, and access to medical advice. Outpatient management is more cost-effective and can minimize missed days of school and work for patients with diabetes and their family members. Important aspects of preventive care in HHS include frequent monitoring and adequate hydration as well as prevention and early treatment of hyperglycemia. Thus, diabetes education and sick-day management should be reviewed periodically in patients with diabetes and should include specific information on when to contact the healthcare provider, blood glucose and A1c goals, use of supplemental short- or rapid-acting insulin during illness, and, most important, the importance of never discontinuing insulin and of seeking immediate medical attention in the case of severe hyperglycemia. In addition, patients with T1DM should be instructed on the use of home blood ketone monitoring during illness and persistent hyperglycemia, which may allow for early recognition of impending ketoacidosis, and in turn may help to guide insulin therapy at home and, possibly, may prevent hospitalization for DKA. Finally, the alarming rise in insulin discontinuation because

of economic reasons as the precipitating cause for DKA in urban patients illustrates the need for healthcare legislation to ensure reimbursement for medications to treat diabetes. Novel approaches to patient education incorporating a variety of healthcare beliefs and socioeconomic issues are critical to an effective prevention program. Furthermore, recent studies in DKA suggest that frequent endocrine clinic visits on a quarterly rather than on an annual basis reduces DKA events significantly as compared to an annual visit [2].

Future prospects

The following are selected research topics and questions proposed to guide the management of patients with DKA and HHS in various hospital settings:

1 The mechanism for low or absent ketones in HHS versus DKA.
2 Left ventricular cardiac status of patients in severe DKA.
3 Resource utilization for the management of patients with mild, moderate, and severe DKA and HHS in various inpatient settings (ICU versus step-down units versus general wards).
4 What are optimal and safe glycemic targets during continuous insulin infusion until resolution of DKA? It is not known if we need to maintain a glucose concentration in the hyperglycemic range between $\sim$150 mg dL^{-1} and 250 mg dL^{-1} until resolution of ketoacidosis and HHS. This recommendation precludes the use of insulin infusion protocols commonly used in critically ill patients with hyperglycemia (glucose target 140–180 mg dL^{-1}).
5 Is the use of bicarbonate needed in patients with severe DKA? Available studies suggest that for pH >6.9–7.0, the use of bicarbonate does not provide any advantage. No prospective randomized studies are available to establish efficacy of the use of bicarbonate in DKA for pH <6.9.
6 What is the role of continuous glucose monitoring (CGM) systems in the acute and post discharge management of patients with hyperglycemic crises? The Endocrine Society Clinical Practice Guideline Committee on the use of CGM recently recommended against the use of this technology in critically ill patients. The use of CGM may have an advantage over bedside point-of-care (POC) testing in that it has the potential to reduce unknown hypoglycemic events that may occur between POC measurements; however, there is concern about the accuracy of CGM at low blood glucose levels.

Management of diabetes: glucose and lipid monitoring, specific subgroups

Type 2 diabetes in obese adolescents: pathophysiology and treatment

Grace Kim and Sonia Caprio

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Key points

- The prevalence of type 2 diabetes (T2DM) is increasing in the pediatric population, particularly in ethnic minorities.
- Adolescents with impaired glucose tolerance have severe insulin resistance and abnormal insulin secretion.
- In comparison to adults, the time course in developing T2DM is more rapid in children and adolescents.
- Insulin resistance is the result of the imbalance of fat deposition in skeletal muscle and abdominal fat.
- Nonalcoholic fatty liver disease is a strong risk factor for T2DM.
- The treatment of T2DM in children and adolescents is a challenge and combination pharmacologic treatment for long-term glycemic control will need to be explored.

Type 2 diabetes in obese youth: a growing challenge

Type 2 diabetes mellitus (T2DM) has emerged as one of the greatest global health challenges of the twenty-first century, projected to affect roughly 1 in 3 individuals born in the year 2000 at some time during their lifetime [1]. Although T2DM was formerly a disease of adulthood, youth-onset T2DM now represents a substantial percentage of new cases of diabetes overall, ranging from 14% in non-Hispanic Whites to 86% in American Indians [2]. Recent population-based data from the SEARCH study (Search for Diabetes in Youth) indicate that diabetes is diagnosed in about 3700 obese youth annually in the USA [2].

Progression from normal glucose tolerance to overt T2DM involves an intermediate stage of hyperglycemia, characterized by impaired fasting glucose (IFG) and/or IGT, now known as prediabetes [3]. Recent reports have documented a high prevalence of prediabetes among children and adolescents [4]. In a multiethnic clinic-based population of obese children and obese adolescents, IGT was detected in 25% of the obese children and 21% of the obese adolescents, and silent T2DM was identified in 4% of the obese adolescents, irrespective of ethnicity [5]. This was the first study to highlight the high prevalence of prediabetes in the midst of the epidemic of childhood obesity [5]. The risk factors associated with IGT in that study were, in order of importance: (1) insulin resistance (estimated by the Homeostatic Model Assessment of Insulin Resistance (HOMA-IR), (2) fasting proinsulin, (3) 2-hour insulin level, and (4) fasting insulin [5].

Cruz et al. found that 28% of obese Hispanic children with a positive family history for T2DM had IGT, but found no cases of T2DM [6]. Gruters et al. reported that the prevalence of IGT was 36.3% among an obese multiethnic cohort of children and adolescents with a risk factor for T2DM [7]. High prevalence of IGT has been also reported in obese children from Thailand [8] and the Philippines [9]. Recent studies conducted in Italy in a large overweight and obese pediatric population reported a prevalence of prediabetes of 12% [10].

Clinical characteristic of T2DM in youth

The TODAY study (Treatment Options for type 2 Diabetes in Adolescents and Youth) the largest ethnically and geographically diverse group of pediatric subjects with T2DM ever assembled, has provided detailed information about the clinical characteristics of the disease in youth [11]. Key emerging important facts about youth-onset T2DM are: higher prevalence in females; presence of moderate to severe obesity; peak of onset at puberty; presence of acanthosis nigricans; greater prevalence among African Americans, Hispanic, and Native American children; strong family history of diabetes; and highly economically disadvantaged families [11]. Of note, 26% of TODAY's participants presented at baseline with hypertension,

13% had microalbuminuria, 79% had a low high-density lipoprotein level, and 10% had hypertriglyceridemia [11].

Beta-cell dysfunction: an early alteration in the development of T2DM

Over the past decade several groups have studied the putative defects underlying the development of T2DM in youth. However, very few studies have described the natural history of the disease in childhood. In obese adolescents relevant information on β-cell function across the spectrum of glucose tolerance have been provided by several cross-sectional and longitudinal studies in which the state-of-the-art modeling of insulin secretion were applied to the OGTT and hyperglycemic clamp tests [12–14]. Employing the hyperglycemic clamp together with mathematical modeling of glucose-stimulated insulin secretion, Weiss et al. investigated the role of insulin secretion and proinsulin processing in glucose regulation in a group of 62 obese adolescents with different glucose tolerance status (30 NGT, 22 IGT, and 10 T2DM) [15]. This study showed that when compared with obese adolescents with a similar degree of insulin resistance, those with IGT and those with T2DM display a progressive loss of glucose sensitivity of β-cell first-phase secretion [12]. In contrast, the homeostatic loop between insulin sensitivity and glucose sensitivity of β-cell second-phase secretion is apparently preserved in IGT but disrupted in T2DM [15]. This is accompanied by alterations in the proinsulin-to-insulin processing, as reflected by an increase in the proinsulin-to- insulin secretion ratio, showing also a failure in the complex post-transcriptional event of insulin production [15]. Thus, IGT obese adolescents are characterized by an alteration of first-phase secretion, and several β-cell defects concur to cause diabetes in childhood [15]. Therefore, in a similar way to those observed in adult subjects [16], almost ~80% of the β-cell function is reduced or lost already at diagnosis [15].

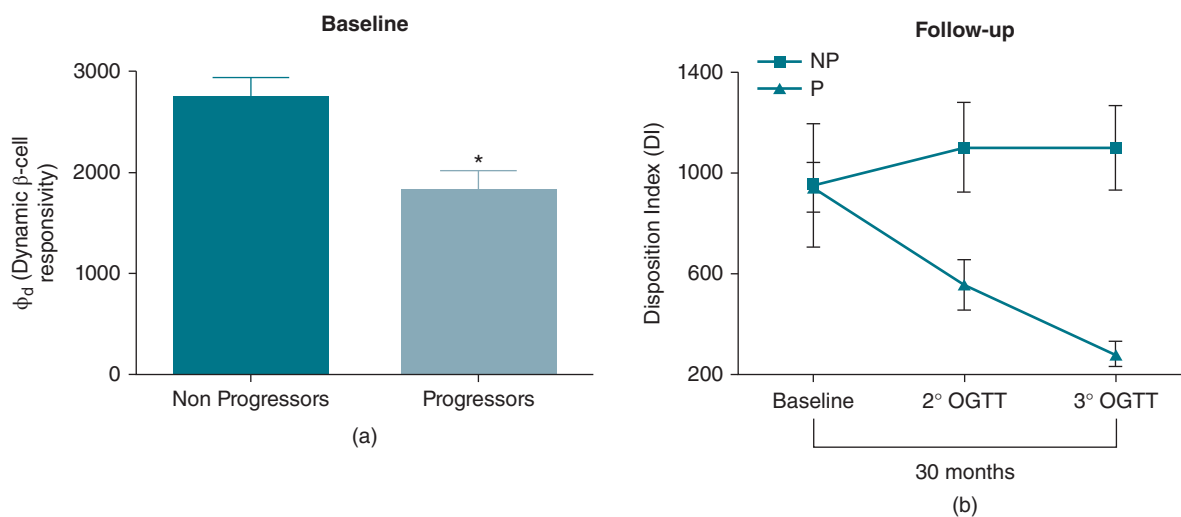
In addition, differences in β-cell function have been described in various prediabetic conditions seen in obese adolescents, such as IFG or IGT or the combined IFG/IGT states [15]. Cali et al. documented that IFG, in obese adolescents, is primarily linked to alterations in glucose sensitivity of first-phase insulin secretion [17]. In contrast, adolescents with IGT are affected by a more severe degree of peripheral insulin resistance and reduction in first-phase secretion. Interestingly, the association between IFG and IGT resulted in a new additional defect in glucose sensitivity of second-phase insulin secretion and by a profound insulin resistance [17]. The role of "pre-existing" β-cell dysfunction risk in obese adolescents with normal glucose tolerance was subsequently revealed by Cali et al. in a longitudinal study in which β-cell function was assessed from OGTT using the Oral C-Peptide Minimal Model [13]. The disposition index (DI) is a measure for β-cell function relative to insulin sensitivity, and is calculated as the product of insulin sensitivity and β-cell function [18]. In adults, DI is a measure that is predictor for the development of T2DM [19]. In a longitudinal study, obese children who progressed to IGT had declining DI values over time compared to those whose glucose tolerance did not worsen (Figure 55.1(b)) [20]. In addition, adolescents who progressed to IGT had lower β-cell function at baseline than adolescents whose glucose tolerance did not worsen (Figure 55.1(a)) [20].


Figure 55.1 (a) Baseline values of the dynamic β-cell responsivity (Fd) in subjects who maintained normal glucose tolerance (NGT; NP, non progressors) and in subjects who developed impaired glucose tolerance (IGT; P, progressors) ($p = 0.04$). (b) Changes of the disposition index (DI) values according to changes in glucose tolerance over the course of approximately 30 months. Subjects who developed IGT (progressors) experienced a progressive decline of overall β-cell function, as assessed by the DI OGTT, oral glucose tolerance test [20]. *$p = 0.04$. Source: D'Adamo 2011 [20].

Natural history of IGT and the development of T2DM

In adults, the process of developing T2DM from a prediabetic state is gradual and may take place over 4–10 years [12]. In a longitudinal study, obese children and adolescents with IGT were followed for <2 years (21months) [12]. Almost half of the subjects (45.5%) reverted to NGT, 30.3% remained IGT, and 24.2% progressed to diabetes [12]. This time course to developing diabetes was strikingly faster in children than adults [12]. Subjects that reverted to normal glucose tolerance weighed less at baseline and gained minimal weight compared to subjects that progressed to have diabetes [12]. In contrast, those who progressed to diabetes were heavier at baseline and gained a significant amount of weight, approximately 27 kg over the study period [12].

Insulin resistance and T2DM: fat accumulation in all the wrong tissues

The muscle

Defects in both insulin action and secretion are important in the pathogenesis of T2DM [21]. The exact timing and relative importance with which these two defects appear in the natural history of T2DM have been a matter of great debate [21]. To address these issues our group studied both cross-sectional and dynamic changes in insulin action and secretion in obese adolescents with IGT. The cross-sectional study revealed profound insulin resistance in the obese adolescents with IGT compared with those with NGT [22]. The insulin resistance was mainly accounted for by a reduction in nonoxidative glucose disposal (storage), since rates of glucose oxidation did not differ significantly between the groups [22]. Similar metabolic defects have been described in adults with overt T2DM [23]. Next to the disturbances in glucose metabolism, fat metabolism is also deranged in IGT subjects. In particular the lipid composition of the skeletal muscle tissue, where most (70%) of the whole glucose disposal occurs, has attracted much attention in the past decade as a major player in the development of muscle insulin resistance [24,25]. This area of investigation has been greatly advanced by the recent development and validation of spectroscopic techniques, which noninvasively and reliably quantify fat stored inside the myocites; the intramyocellular fat (IMCL) [25]. Strong positive correlations between insulin resistance and IMCL have been reported in offspring of T2DM subjects, suggesting that a high IMCL content may be involved in the development of insulin resistance [26–28]. Using 1H-NMR in our metabolic studies to gather information on the muscle lipid composition we found an excessive accumulation of IMCL in the soleus muscle of IGT obese adolescents compared to age and adiposity matched NGT obese adolescents [22]. Using univariate analysis we found that IMCL content was inversely correlated with the glucose disposal

($r = -0.51$; $p < 0.01$) and with nonoxidative glucose metabolism in the two groups together ($r = -0.45$; $p < 0.03$) [22]. This study offered a novel insight into the pathogenesis of prediabetes in obese children and adolescents, namely that changes in glucose homeostasis are closely linked with altered partitioning of fat in skeletal muscle [22]. It is not entirely clear at the present time what leads to an overaccumulation of lipid in skeletal muscle tissues. Defects in muscle fatty acid oxidation and increased fatty acid flux to muscle have both been considered as potential players [24]. Triglyceride accumulation per se in muscle does not cause insulin resistance. Rather, overaccumulation of various lipid moieties in myocytes, such as long chain fatty acyl-CoA, have been shown to interfere directly with insulin signaling and glucose transport [29–32].

The abdominal fat: a complex layer of metabolically different adipose tissues

Visceral fat accumulation is known to be associated with features of the insulin resistance syndrome in adults and obese children [33], although the nature of this relationship and the relative importance of visceral versus subcutaneous abdominal fat remains a matter of debate. Altered distribution of fat between the subcutaneous and intra-abdominal compartment is associated with the development of IGT in obese adolescents [34]. The visceral-to-subcutaneous ratio was significantly greater in the IGT than in the NGT group. Both the enlarged visceral depot ($r = -0.63$; $p < 0.01$) and the visceral-to-subcutaneous ratio ($r = -0.66$; $p < 0.01$) were inversely related to the insulin-stimulated glucose metabolism [34]. These studies, therefore, suggested that insulin resistance is the result of the imbalance of fat distribution in both the abdominal adipose and skeletal muscle tissues. Furthermore, our data are consistent with results obtained in both human and animal models of lipodystrophy, in which there is an absence of subcutaneous adipose tissue, leading to increased circulation of lipids and their accumulation in both myocytes and the visceral depot [28,35]. Thus, it appears that the ability of peripheral subcutaneous fat tissue to vary its storage capacity is critical for regulating insulin sensitivity and ultimately protecting against diabetes. Consistent with this hypothesis is the evidence derived from the use of thiazolidinediones, which improve insulin sensitivity while increasing subcutaneous abdominal fat, but decreasing the visceral and liver fat depots [36,37].

The liver

Like T2DM, nonalcoholic fatty liver disease (NAFLD) is a comorbidity associated with obesity [38]. NAFLD is described as hepatic fat accumulation not caused by alcohol use [39]. NAFLD represents a spectrum that ranges from simple fatty deposition to inflammation, to fibrosis and cirrhosis [40]. Fatty liver may precede the onset of T2DM [38], and is a marker of insulin resistance and glucose dysregulation in children and adults [41]. Several adult studies have shown that high levels of hepatic enzymes (i.e., alanine aminotransferase (ALT))

forecast the development of T2DM [42]. In a multiethnic group of 392 adolescents, glucose and lipid metabolism measures were abnormal even at ALT levels in the upper half of normal range [41]. Using a noninvasive method, hepatic fat content was measured with fast magnetic resonance imaging, where HFF equal to or above 5.5% is suspicious for hepatic steatosis [41]. Thirty-two percent of subjects had increased hepatic fat fraction [41]. Hepatic steatosis was associated with decreased insulin sensitivity, and increased triglycerides and visceral fat (Figure 55.2) [41]. The connection between abdominal obesity and fatty liver may be due to excess free fatty acids travelling to the liver overflowing from the visceral fat compartment [33]. Subjects with fatty liver had a higher prevalence of metabolic syndrome [41].

Indeed, fatty liver is considered to be the hepatic component of metabolic syndrome [41]. In order to understand the potential role of fatty liver in the onset of T2DM in obese youth, we have recently assessed whether the severity of hepatic steatosis affects the presence of glucose metabolism dysregulation in a multiethnic cohort of obese adolescents [43]. Independent of obesity, the severity of fatty liver was associated with the presence of prediabetes conditions (IGT and IFG/IGT) and hepatic steatosis,

independently, predicted prediabetes in obese adolescents [43]. In addition, paralleling the severity of hepatic steatosis, there was a significant decrease in insulin sensitivity and impairment of β-cell function (assessed by using the DI) [43]. These findings suggest that the intrahepatic fat accumulation is a strong risk factor for T2DM, and its early identification is critical to prevent the development of metabolic complications in youth [43].

Treatment for T2DM: lessons from the TODAY study

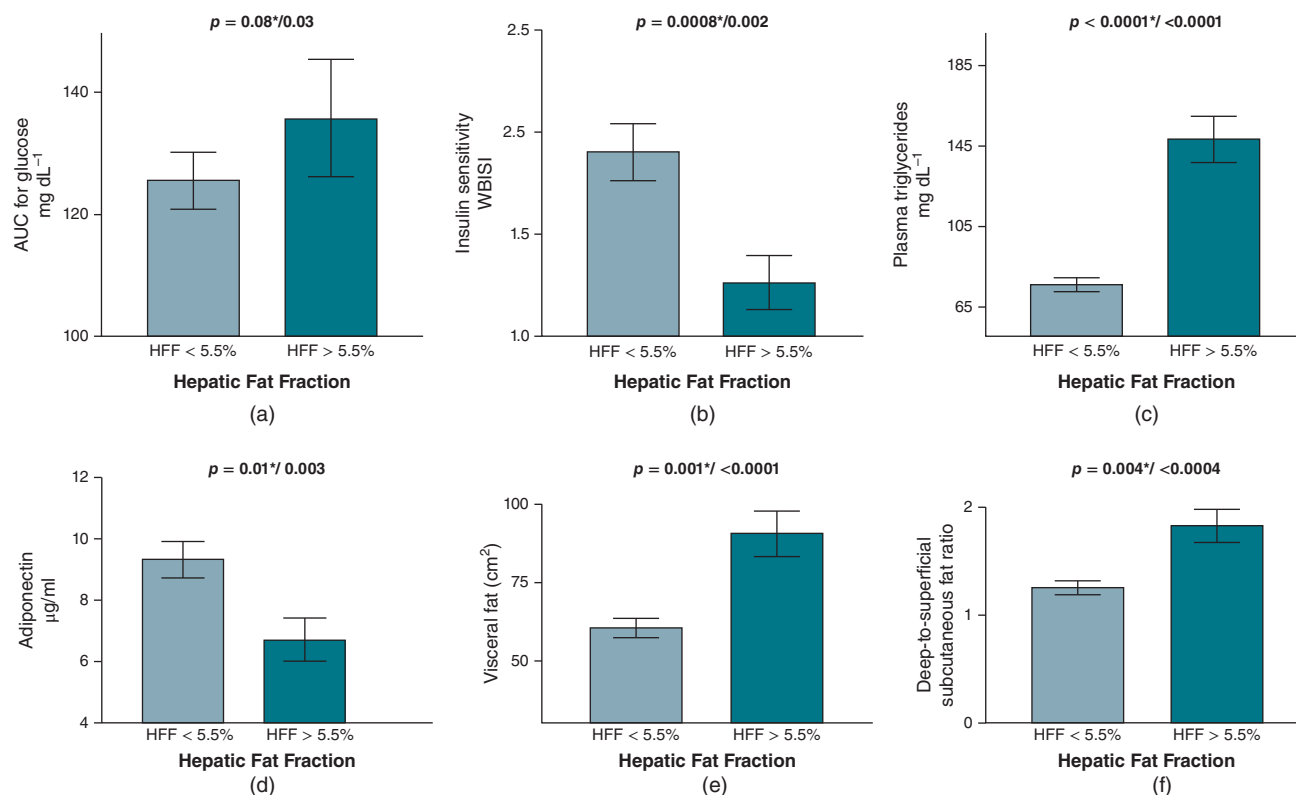
Despite the escalating rates of obesity-driven T2DM in youth, therapeutic options remain limited to metformin, the only FDA-approved oral hypoglycemic agent, and insulin when the former fails [44]. Even though metformin was effective in the short term over 16 weeks, it remained unknown whether this effect was durable [45] until the results of TODAY (Treatment Options for type 2 Diabetes in Adolescents and Youth) showed more than 50% failure rates on metformin [46]. The TODAY study was a multicenter, randomized (699 overweight youth between 10 and 17 years of age, with T2DM of


Figure 55.2 Metabolic characteristics and abdominal fat partitioning in subjects with low versus high HFF. The *p* values are for differences between low HFF (<5.5%) and high HFF (≥5.5%), both unadjusted and adjusted (*) for age, gender, race/ethnicity, and BMI *z*-score. <2 years' duration) clinical trial which compared metformin monotherapy with metformin plus rosiglitazone, and metformin plus intensive lifestyle intervention on time to treatment failure, that is, loss of glycemic control defined as either HbA1c ≥ 8% over a 6-month period or inability to wean from temporary insulin therapy within 3 months of acute metabolic decompensation [46]. The results revealed that the combination of metformin and rosiglitazone was superior to metformin alone in sustaining durable glycemic control, and metformin plus lifestyle was intermediate [46]. Treatment with metformin alone was inadequate for maintaining long-term acceptable glucose control in 51.7% of youth over an average follow-up time of 46 months [46]. In the metformin plus rosiglitazone treatment the failure rates were 38.6% and in the lifestyle plus metformin the failure rates were much higher at 46.6% [46].

This randomized controlled trial indicates that treatment of T2DM in youth is a growing challenge [46]. T2DM seem to have an accelerated course in youth, which could be why metformin alone had a higher than expected failure rate [46]. Given that rosiglitazone has been linked to higher risk of heart attacks in adults, the TODAY research group agreed that it cannot be recommended to treat T2DM in obese adolescent [46]. Even more discouraging were the results that indicated the lack of significant success of the lifestyle arm to achieve durable glycemic control and significant weight loss [46]. Although this metabolic condition is strongly driven by a poor lifestyle, in the TODAY trial the lifestyle program together with metformin did not translate into better glycemic control for a substantial number of teens [46]. The results of the TODAY trial suggest that treatment of T2DM is a challenge in this age group [46]. Achievement of long-term glycemic control may require combination treatment with pharmacologic agents that target both insulin sensitivity and β-cell function or insulin therapy very early on in the course of the disease [46].

Diabetes in pregnancy

Yoel Toledano, Eran Hadar and Moshe Hod
Division of Maternal Fetal Medicine, Helen Schneider Hospital for Women, Rabin Medical Center, Petah-Tiqva, Israel

Key points

- Pregnancy is characterized by insulin resistance, developing during the second half of gestation. When hyperinsulinemia cannot compensate for exaggerated postprandial hyperglycemia, gestational diabetes develops.

- The perturbations of glucose homeostasis in pregnancy are classified into two main categories: gestational (GDM) and pregestational diabetes mellitus.

- Generally, it is estimated that diabetes (type 1, type 2, and GDM) occurs annually in 1–14% of all pregnancies, and specifically in 6–7% of pregnancies in the United States.

- Selective or universal screening for gestational diabetes mellitus should be determined by population characteristics. A new method for diagnosis of gestational diabetes mellitus has been recently suggested.

- Pregnancy complicated by diabetes is associated with abortions, major congenital malformations, macrosomia, and increased perinatal mortality.

- The key to improving pregnancy outcomes in women with diabetes is strict glycemic control.

- Alternatives for gestational diabetes treatment are medical nutrition and physical activity therapy either alone or in combination with glyburide, or insulin.

- Continuous glucose monitoring technology uncovers previously undetected glucose perturbations and glucose trends and is a helpful adjunct to conventional therapy.

- Preconceptional evaluation for women with pregestational diabetes should be encouraged.

- Postpartum screening for type 2 diabetes (T2DM) should be performed at 6–8 weeks in all women with gestational diabetes mellitus.

Maternal adaptation to pregnancy

Variable physiologic changes begin shortly after implantation [1]. Hyperplasia and hypertrophy of the β cells in the islets of Langerhans are ascribed to stimulation by estrogen and progesterone. Glucose crosses the placenta by facilitated diffusion during early pregnancy to supply glucose requirements of the fetus. Maternal fasting hypoglycemia may occur as a result of this enhanced glucose transport. In contrast to a seemingly normal basal insulin secretion, postprandial insulin levels are elevated, mainly due to an increase in synthesis and secretion.

Insulin resistance, developing during the second half of pregnancy, is related to an elevation of several hormones, including human placental lactogen, glucocorticoids and progesterone, as well as free fatty acids and tumor necrosis factor-α. Furthermore, glucose ingestion in late pregnancy results in higher and more sustained levels of glucose and insulin compared to nonpregnant subjects. In addition, glucagon is suppressed to a greater degree.

Recently, the glycemic profile in the second half of nondiabetic pregnancy was characterized by studies using continuous glucose monitoring (CGM) [2]. Hence, it is currently possible to define better glycemic targets in order to mirror normoglycemia in pregnant diabetic women. In nonobese, nondiabetic, subjects, the difference in glucose levels between fasting and preprandial values during the day was minimal. This suggested that fasting plasma levels may reflect preprandial values [2]. However, mean blood glucose levels during the night-time (23:00–06:00) were significantly lower than daytime levels. In a recent study, CGM confirmed that diurnal glucose patterns throughout the day are reduced by 20% and also that the percent of time in hypoglycemia is significantly higher in the pregnant versus nonpregnant states [3].

Classification of glucose abnormalities in pregnancy

The perturbations of glucose homeostasis in pregnancy are classified into two main categories:

1 Gestational diabetes (GDM), first defined by O'Sullivan in 1961, as "carbohydrate intolerance of varying severity with onset or first recognition during pregnancy." This condition,

---

based mainly on a standardized glucose tolerance test, is the most common type of diabetes in pregnancy. GDM is stratified by fasting plasma glucose and treatment modality to A1 (diet) and A2 (pharmacologic treatment).

2 Pregestational diabetes includes all women whose glucose intolerance is discovered before conception, including type 1 (T1DM) and type 2 diabetes mellitus (T2DM), without differentiating between them. They are further categorized according to length of disease and the presence of microvascular or other end-organ complications.

Additionally, the ongoing epidemic of obesity and diabetes has led to increased incidence of T2DM in women of childbearing age. Hence, it is diagnosed more frequently during pregnancy in the last years. Consequently, it is reasonable to screen women with risk factors for T2DM already at their first prenatal visit, using standard criteria for the diagnosis of diabetes [4].

Epidemiology of diabetes in pregnancy

Based on both national birth statistics and small community studies, it is estimated that diabetes (T1, T2, and GDM) occurs annually in 1–14% of all pregnancies. Specifically, it has been demonstrated that approximately 6–7% of pregnancies in the United States are complicated by diabetes mellitus [5]. Actually, fetal or maternal complications are reported in an estimated 400,000 live births in the USA each year. More than 90% of them are linked to maternal glucose abnormalities, especially large-for-gestational-age infants and macrosomia [6]. When other complications are considered, including spontaneous abortion, fetal malformation (principally found in pregestational diabetes), shoulder dystocia, preeclampsia, and delivery by cesarean section, the incidence of diabetes in pregnancy rises to 13%. Moreover, GDM is a major public health problem with a growing magnitude. It is estimated at up to 20% by evidence collected from high-prevalence groups, such as ethnic minorities (American Indians, Native Hawaiians and other Pacific Islanders, and Hispanics).

It is estimated that between 0.4% and 2% of all births are complicated by pregestational diabetes. Indeed, differentiating the number of births complicated by T1DM from those complicated by T2DM is difficult as the prevalence of each of them varies by both race and age. Notably, it is assumed that the prevalence of pregnancies complicated by pregestational diabetes will increase due to several factors, including increased incidence of obesity in women of childbearing age, increased incidence in T2DM among adolescents and women younger than 25 years of age, increased birth rate among adolescents, and population growth among groups with higher risk of diabetes.

The prevalence of GDM is directly related to the prevalence of T2DM in a given population. GDM prevalence in the US is around 5–6%, accounting for at least 85% of diabetes occurring in pregnancy [5]. However, controversy in the epidemiology of GDM concerns debates on who should be screened, when

Table 56.1 Risk factors for gestational diabetes mellitus

Advanced maternal age
Maternal obesity
High parity
Previous delivery of a macrosomic infant
Family history of type 2 diabetes mellitus
Maternal short stature
Polycystic ovary disease
High levels of saturated fat in the diet
Prior gestational diabetes
Prior neonatal death
Prior cesarean delivery
Previous stillbirth or congenital malformations
High blood pressure during pregnancy
Multiple pregnancies

screening should occur, screening test criteria, and diagnostic test criteria [6].

Table 56.1 presents risk factors for GDM. Accumulation of risk factors increases the risk. Moreover, the offspring of diabetic mothers are at an increased risk for future insulin resistance. Taking into account the increased prevalence of obesity and T2DM at this era, GDM occurrence may significantly rise, with a vicious cycle of insulin resistance, obesity, diabetes, and their consequent complications in future generations.

Diagnosis of gestational diabetes mellitus

The basis for the diagnosis of gestational diabetes mellitus (GDM) was laid down by O'Sullivan et al. in the 1960s [7]. They suggested the criteria for an abnormal 100 g oral glucose tolerance test (OGTT), based on an outcome set to identify women at risk for subsequent diabetes. Thus, the major shortcoming of those criteria is the lack of correlation to adverse pregnancy outcomes. The currently accepted guidelines for the diagnosis of GDM were presented in the Fourth International Workshop-Conference on GDM [8] and were endorsed by several key organizations [4,9]. Strategies for screening and diagnosis of GDM, will be discussed in the following sections, and are summarized in Figure 56.1 and Table 56.2.

Screening and its cost-effectiveness

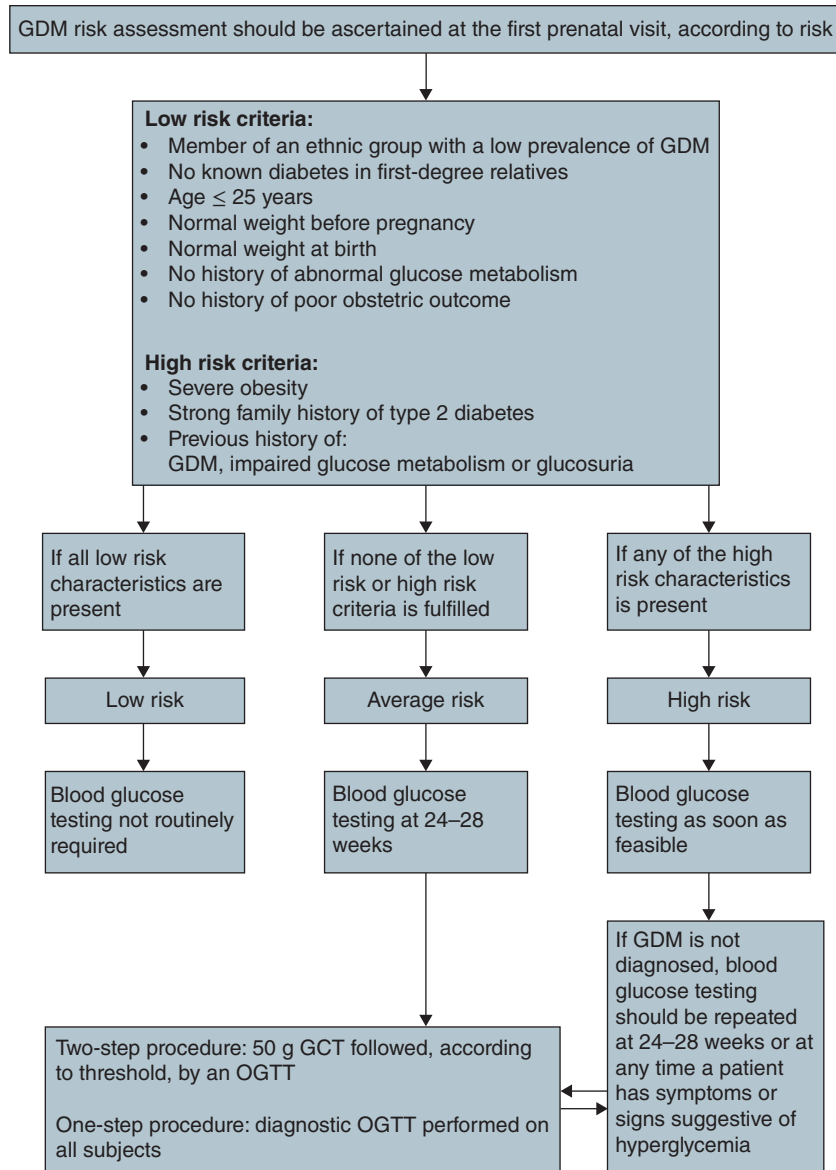
Screening recommendations range from the inclusion of all pregnant women (universal) to the exclusion of all women except those at risk (selective). Screening policy should be determined locally, depending upon population characteristics, local prevalence and preference. It is achieved by either selecting high-risk populations or a 50 g glucose challenge test (GCT). The American Congress of Obstetricians and Gynecologists (ACOG) [9] recommends universal screening for all pregnant women, to be done between 24–28 weeks of gestation, except women who meet all the low-risk criteria. The American Diabetes Association (ADA) [4] supports selective screening depending upon risk factors (Table 56.1). Risk assessment


Figure 56.1 Strategy for screening and diagnosis of gestational diabetes mellitus.

Table 56.2 Diagnosis of gestational diabetes mellitus (GDM) by an oral glucose tolerance test (OGTT) [8]

	100 g glucose				75 g glucose	
	Carpenter & Coustan criteria[a]		NDDG criteria[b]		mg dL^{-1}	mmol/l
	mg dL^{-1}	mmol L^{-1}	mg dL^{-1}	mmol L^{-1}		
Fasting	95	5.3	105	5.8	95	5.3
1 hour	180	10.0	190	10.6	180	10.0
2 hour	155	8.6	165	9.2	155	8.6
3 hour	140	7.8	145	8.0	–	–

[a] Plasma/serum glucose
[b] Plasma glucose

should be carried for all pregnant women at the first prenatal follow-up, to be made as early as possible during pregnancy (Figure 56.1). In contrast, other organizations have stated that there is insufficient evidence to make a recommendation for or against GDM screening [10].

The main screening tool is the GCT, preformed with or without overnight fasting, and involves plasma glucose measurement 1 hour after ingestion of 50 g glucose. Glucose concentrations of 130–140 mg dL^{-1} (7.2–7.8 mmol L^{-1}) are considered as the positive cutoff, indicating the need for a diagnostic OGTT. A threshold set to 130 mg dL^{-1} has a sensitivity of nearly 100% with 23% of women requiring an OGTT. A 140 mg dL^{-1} cutoff yields a sensitivity of nearly 90%, with a 15% positive screen rate [11]. Importantly, about 10% of those with screening results of 130–139 mg dL^{-1} will have GDM; however, the lower threshold is associated with a 12% increase in the cost for GDM diagnosis [12]. Because the precise cost–benefit ratio for diagnosing GDM remains unresolved, either threshold is acceptable. The selection should be decided upon local considerations. Thus, in high-prevalence countries it is reasonable to use the lower threshold (for increased sensitivity), and the higher cut-off may be favored (for lower cost) when the prevalence is low.

Recently, the cost-effectiveness of GDM screening and intervention was studied in India and Israel, settings with contrasting epidemiologic and cost environments [13]. Significantly, GDM interventions are highly cost-effective in both settings, by World Health Organization standards.

Diagnosis of GDM: the traditional criteria

The most commonly accepted method of GDM diagnosis is a 100 g OGTT, using either the National Diabetes Data Group (NDDG) criteria [14] or the Carpenter and Coustan criteria [15] (Table 56.2). The test should be performed in the morning after an 8–14-hour overnight fast and after at least 3 days of unrestricted diet (>150 g carbohydrate per day) and physical activity. Plasma glucose is measured at fasting, 1, 2, and 3 hours following glucose load. Two or more of glucose concentrations must be met or exceeded for a positive diagnosis. Alternatively, new criteria are listed in the following sections.

The HAPO Study

As previously mentioned, the diagnostic value of the O'Sullivan criteria and the derived guidelines are of limited value, as the true levels of hyperglycemia that have an impact on pregnancy outcomes, were not established. In order to establish an evidence base to the diagnosis of GDM, the hyperglycemia and adverse pregnancy outcome (HAPO) study was designed [16].

The HAPO was a prospective, observational, study held in 15 medical centers from 9 countries with 23,316 women. Each participant, at approximately 28 weeks, preformed a 2-h 75-g OGTT. Caregivers and participants remained blinded to the results unless glucose values indicated overt diabetes or hypoglycemia. The results demonstrated an association between increasing levels of fasting, 1-h and 2-h plasma glucose post a 75-g OGTT, to the four primary endpoints of the study: birth weight above the 90th percentile, cord blood C-peptide level above the 90th percentile, primary cesarean delivery, and clinical neonatal hypoglycemia. Positive correlations were also found between increasing plasma glucose levels to the five secondary outcomes: premature delivery, shoulder dystocia or birth injury, intensive neonatal care admission (NICU), hyperbilirubinemia, and preeclampsia.

IADPSG criteria: a new approach for the diagnosis of diabetes in pregnancy

Based on the results of the HAPO, with supplementary and ancillary investigations, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) suggested a new strategy for diabetes diagnosis during pregnancy (Tables 56.3, 56.4, and 56.5) [4,17]. At the first prenatal visit, all (universal) or only high-risk women (selective) should be tested for either fasting plasma glucose (FPG), hemoglobin A1c (HbA1c) or random plasma glucose (RPG). High-risk criteria include: pre-pregnancy obesity, family history of T2DM, prior GDM and known carbohydrate intolerance or glucosuria. Recently, the value of FPG for the diagnosis of GDM at the first prenatal visit was evaluated in a Chinese population [18]. It was suggested that FPG value of 6.10–7.00 mmol L^{-1} (110–126 mg dL^{-1}), and not 5.10–6.00 mmol L^{-1} (92–109 mg dL^{-1}), at the first prenatal visit should be considered as the criterion for diagnosis of GDM.

The next phase, at 24–28 weeks of gestation, includes a single diagnostic step with a 2-h 75-g OGTT. The IADPSG criteria allow the diagnosis of overt diabetes to be made during pregnancy, an option not available in the previously mentioned guidelines. Importantly, the suggested cut-offs are lower than those currently acceptable, which will lead to a higher prevalence of GDM, but these cut-offs are based on evidence extrapolated from the HAPO study. At the present time, the debate as to whether or not to adopt the IADPSG criteria is still ongoing. The ADA has already adopted these recommendations [4]. The ACOG has issued a committee opinion, not supporting the IADPSG single-step recommendations [19] due to lack of evidence that the identification and treatment of women, based on the IADPSG criteria, will lead to clinically significant improvements in maternal and neonatal outcomes. Rather, this management can cause a significant increase in healthcare costs. The WHO and the National Institutes of Health (NIH) are expected to publish guidelines in the near future.

Using the Israeli HAPO study data, Kalter-Leibovici et al. [20] found that adoption of IADPSG recommendations would increase GDM diagnosis by ~50% (from 6% to 9%). Risk stratification may reduce overtreatment in one third of IADPSG-positive women. FPG ≥ 89 mg dL^{-1} or BMI ≥ 33.5 kg m^{-2} at 28–32 weeks of gestation detected proportions of adverse outcomes similar to IADPSG criteria. Hence, FPG or BMI may be a practical screening alternative.

Table 56.3 Strategy for the detection and diagnosis of hyperglycemia disorder in pregnancy [17]

1st prenatal visit	Measure fasting plasma glucose (FPG), hemoglobin A1c (HbA1c), or random plasma glucose (RPG) on all or only high-risk women.	If results indicate overt diabetes as per Table 56.4 → Preexisting (overt) diabetes
		If results not diagnostic of overt diabetes as per Table 56.4 and FPG ≥ 5.1 mmol L^{-1} (92 mg dL^{-1}) but < 7.0 mmol L^{-1} (126 mg dL^{-1}) → GDM
		If results not diagnostic of overt diabetes as per Table 56.4 and FPG < 5.1 mmol L^{-1} (92 mg dL^{-1}) → test for GDM during 24–28 weeks, with a 75 g OGTT
24–28 weeks of gestation	75 g OGTT on all women not previously diagnosed with overt diabetes or GDM	If fasting plasma glucose ≥ 7.0 mmol L^{-1} (126 mg dL^{-1}) → Preexisting diabetes
		If one or more values equals or exceeds thresholds as per Table 56.5 → GDM
		If all values less than thresholds indicated as per Table 56.5 → Normal

Table 56.4 Threshold values for diagnosis of overt diabetes in pregnancy [17]

Measure of glycemia	Threshold	
Fasting plasma glucose	≥7.0 mmol L^{-1}	≥126 mg dL^{-1}
Hemoglobin A1c	≥6.5%	–
Random plasma glucose	≥11.1 mmol L^{-1}	≥200 mg dL^{-1}

If a random plasma glucose is the initial measure of glycemia, the tentative diagnosis of overt (preexisting) diabetes should be confirmed by fasting plasma glucose or hemoglobin A1c

Table 56.5 Glucose threshold values for diagnosis of GDM [17]

Glucose measure	Glucose threshold	
	mmol L^{-1}	mg dL^{-1}
Fasting plasma glucose	5.1	92
1-hour post 75-g OGTT	10.0	180
2-hour post 75-g OGTT	8.5	153

Adverse pregnancy outcomes in gestations complicated by diabetes

Pregnancies complicated by diabetes, whether pregestational or gestational, are subject to short- and long-term complications which may arise throughout pregnancy, delivery, and postpartum. Adverse outcomes may inflict the diabetic mother as well as her fetus, neonate, child, and adult offspring (Table 56.6).

Glucose and possibly other metabolites account for the pathogenesis of these adverse outcomes, as they create an altered environment in which the fetus is exposed to changes in gene expression, free oxygen radicals, cellular damage, impaired metabolic environment and increased teratogenesis [21]. Hence, the rate of these complications is closely related to the degree of pregestational, periconceptional, and antenatal glycemic control.

Congenital anomalies

Major congenital anomalies are the primary contributor to perinatal mortality and morbidity for the offspring of a mother with pregestational diabetes, accounting for 30–50% of perinatal mortality. There is a three- to fivefold increase in the incidence of congenital anomalies in infants of pregestational diabetic mothers, rising from approximately 2% incidence in the normal population to 6–11%. The congenital malformation rate is inversely related to maternal age at onset of diabetes and directly related to the level of glycemic control prior to pregnancy and during early pregnancy [22]. Poor glycemic control exposes abnormal levels of glucose, insulin and ketones which are involved in the pathogenesis of malformations. Anomalies occur early in pregnancy, during the period of organogenesis, usually up until the 7th week of gestation. They do not involve a specific organ. Rather, cardiac, central nervous, genitourinary and gastrointestinal systems may be implicated. Specific anomalies include neural tube defects, holoprosencephaly, ventricular septal defects, and transposition of the great vessels. Caudal dysplasia is highly characteristic, and although occurs more frequently in diabetic pregnancies, it is still rare and not pathognomonic. The critical time for glycemic control is at a time period where women are either not pregnant, unaware of their pregnancy or are aware but still not seeking prenatal care. Therefore, management and

Table 56.6 Gestational and pregestational diabetes-associated morbidity during pregnancy

Maternal	Fetal	Neonatal	
Hypertensive disorders	Abortion	Short term (baby)	Long term (child & adult)
Urinary and genital tract infections	Stillbirth	Respiratory morbidity	Type 2 diabetes mellitus
Cesarean section	Congenital anomalies	Neonatal intensive care unit admission	Obesity
Future type 2 diabetes mellitus	Large-for-gestational-age and macrosomia	Hypoglycemia	Gestational diabetes (if female)
		Hyperbilirubinemia	
	Preterm labor and delivery	Hypocalcemia	
Polyhydramnios			
Instrumental delivery			
Traumatic labor			
Birth injury and shoulder dystocia			

counseling of women with diabetes should begin before conception. Unfortunately, less than 20% of diabetic women undergo pre-pregnancy counseling. Lack of preconceptional care and pre-pregnancy uncontrolled diabetes are associated with an increased malformation rate. Appropriate pregnancy planning and glycemic control may decrease the rate of congenital anomalies to a comparable rate of the background population. Mean glucose level < 100 mg dL^{-1} (5.6 mmol L^{-1}) is associated with a low incidence of anomalies, as well as HbA1c of less that 7%.

Spontaneous abortions
The risk for a spontaneous abortion is also correlated to the degree of glycemic control. Good control, with normal HbA1c, reduces the risk of miscarriage to similar levels of the nondiabetic population.

Stillbirth
Stillbirth was a common complication in diabetic pregnancies and has become a rare event in current practice, nonetheless devastating. Hyperglycemia is involved in the pathogenesis of several factors leading to stillbirth — mainly congenital anomalies, fetal hypoxemia and acidemia, placental insufficiency, and macrosomia. Maternal hyperglycemia is translated into hyperinsulinemia, mediated by hyperplasia of fetal pancreatic islet cells. Pedersen and others [23,24] have linked it to cord blood acidemia and hypoxemia, which are related to increased rates of stillbirth. As for other complications, stillbirth is inversely related to the level of glycemic control. Mean blood glucose <100 mg dL^{-1} is associated with low perinatal mortality rate.

Fetal demise related to inappropriate metabolic control occurs during late 3rd trimester, and is more pronounced in pregnancies complicated with hypertension, vascular complications, polyhydramnios, growth restriction, and mainly in those with T1 and T2DM.

Macrosomia and large-for-gestational-age
Macrosomia is defined as birth weight above 4000 g and large-for-gestational-age (LGA) as birth weight above the 90th percentile, according to sex and gestational age. Macrosomia is related to increased risk of stillbirth, shoulder dystocia and birth trauma, and an increased rate of operative and cesarean deliveries. Good glycemic control may decrease the rates of macrosomia from 30–50% to as low as 0–22%, depending on glucose values. Tight glycemic control leads to 0%, 9% and 11% macrosomia rates with respective mean blood glucose values of 80–87 mg dL^{-1}, less than 110 mg dL^{-1}, and 105–121 mg dL^{-1} [25–27]. It has been suggested that 3rd trimester nonfasting glucose values, especially the 1-h postprandial glucose is best correlated with the risk of macrosomia.

Detection and treatment of diabetes in pregnancy

Diabetes in pregnancy is a special situation. On one hand, it is important to control hyperglycemia in the mother. On the other hand, preventing the deleterious effects of sugar excursions on the developing fetus is crucial. Until 1980 physicians were advising diabetic women against childbearing due to grave consequences of diabetes in pregnancy. However, as medical knowledge and technologies for treating diabetes before, during, and after pregnancies improved, the prognosis of such pregnancies has greatly improved.

Glycemic control targets
The single most important step to achieving minimal morbidity and mortality rates in GDM is to establish near-normal metabolic control. The complication most clearly correlated to maternal hyperglycemia, specifically maternal postprandial hyperglycemia, is fetal macrosomia. In fact, controlling postprandial glucose levels reduces macrosomia, neonatal hypoglycemia, and cesarean delivery as compared to managing preprandial glucose levels alone [28]. From these studies it is apparent that therapy for pregnant women with diabetes should be targeted to treat 1–2-h postprandial glucose coincident with

Table 56.7 Glucose target values and regular insulin dose during labor and delivery

Insulin dose (units)	Glucose levels	
	mg dL^{-1}	mmol L^{-1}
1–2 units per hour	95–150	5.3–8.3
2 units i.v. push	151–180	8.4–10.0
3 units i.v. push	181–220	10.1–12.2
4 units i.v. push	>220	>12.2

the postprandial hyperglycemia peak (Table 56.8). Nevertheless, controlling of preprandial and nocturnal glucose levels is of paramount importance as well (Table 56.8).

Preconception care for pregestational diabetes

Preconception counselling for women with pregestational diabetes mellitus is of paramount importance and should be encouraged. As congenital anomalies and spontaneous abortions are serious complications in pregestational diabetes, a preconception counselling is beneficial and cost-effective. If strict glycemic control can be safely achieved, the recommended pre-pregnancy HbA1c targets are <6.1% (NICE) [29] and <7% (ADA) [4]. An evaluation of glycemic control, hypoglycemic symptoms and blood pressure should be performed. A survey for diabetes vascular complications is advisable, including a retinal and neurologic examination, a renal function (eGFR or creatinine clearance), a urinary microalbumin excretion test, and, in selected patients, an electrocardiogram. Thyroid function studies should be obtained in patients with T1DM due to comorbidity. Folic acid should always be prescribed as part of preconception care, especially in women with diabetes given their increased risk of neural tube defects.

Diet and behavioral adjustments

Diet is the foundation of treatment for all types of diabetes. Importantly, patient education and adapted physical exercise routines should be combined with the diet plan. Currently, two nutritional approaches are recommended: decreasing the proportion of carbohydrates to 35–40% in a daily regimen of three meals and three or four snacks, and lowering glycemic index carbohydrates for approximately 60% of daily intake. A regimen of smaller, more frequent, meals leads to better satiety and compliance, with a reduction of postprandial glucose peaks. Of note, insulin resistance is highest in the morning. Postprandial glucose levels are directly influenced by the amount of carbohydrates in the consumed food. Therefore, carbohydrate-based calories should be consumed at later times of the day, and breakfast should only be a small meal.

The assignment of daily caloric intake is similar for gestational and pregestational diabetes. It is calculated based on pre-pregnancy BMI and according to actual pregnancy weight (20–25 kcal kg^{-1} for obese women and 30–35 kcal kg^{-1} for nonobese women). Postprandial blood glucose levels and insulin sensitivity may improve control by an appropriate exercise program. However, pregnant diabetic women need to be willing as well as able (socioeconomic limitations, obesity, multiparity) to participate. Pharmacologic agents should be prescribed for patients with GDM who fail to achieve the desired level of glycemic control.

Table 56.8 Capillary blood glucose and HbA1c target values for patients with diabetes in pregnancy

	ACOG recommendations [9,19]	ADA recommendations [4]
GDM		
Fasting glucose	≤95 (5.3)	≤95 (5.3)
1-hour postprandial glucose	≤130–140 (7.2–7.8)	≤140 (7.8)
2-hour postprandial glucose	≤120 (6.7)	≤120 (6.7)
Pregestational diabetes		
HbA1c, %	≤6	<6
Capillary blood glucose, mg dL^{-1} (mmol L^{-1})		
Fasting glucose	≤95 (5.3)	60–99 (3.3–5.5)
Preprandial glucose	≤100 (5.6)	60–99 (3.3–5.5)
1-hour postprandial glucose	≤140 (7.8)	100–129 (5.6–7.2)
2-hour postprandial glucose	≤120 (6.7)	100–129 (5.6–7.2)
Mean capillary glucose	≤100 (5.6)	
Bedtime glucose		60–99 (3.3–5.5)
Overnight glucose	Not <60 (3.3)	60–99 (3.3–5.5)

Insulin treatment

There is a gradual increase in insulin requirement throughout pregnancy: 0.7 units $kg^{-1} d^{-1}$ in the first trimester; 0.8 units $kg^{-1} d^{-1}$ at week 18, 0.9 units $kg^{-1} d^{-1}$ at week 26, and 1.0 units $kg^{-1} d^{-1}$ from week 36 until delivery. In order to mimic the physiologic insulin secretion throughout the day, it is essential to pair rapid-acting insulin analogues with intermediate or long-acting insulins.

Long-acting insulin analogues

Two insulin analogues have a prolonged basal activity: insulins detemir and glargine. They function as basal, nonmeal-related, insulin during the day. Only detemir was studied before and during pregnancy in a large randomized controlled trial of patients with T1DM [30]. Treatment with detemir resulted in a noninferior HbA1c during late gestation and similar maternal hypoglycemia rates compared with NPH insulin. In addition, perinatal morbidity and mortality were comparable, and no specific safety issues were identified [31]. However, several retrospective analyses have demonstrated that glargine may also be safe in pregnancy [32–34]. Indeed, results from a transplacental transfer study showed that insulin glargine has not crossed the placenta at therapeutic concentrations [35]. Degludec is a new ultralong-acting insulin on the horizon. Randomized controlled studies should be established for its use in pregnancy.

Intermediate-acting insulin

Neutral protamine Hagedorn (NPH) insulin has an 8-hour duration. Thus, it is an intermediate-acting insulin. A basal insulin action in a pregnant woman can be attained by three injections of NPH. However, the risk of hypoglycemia is increased, particularly at night, due to an insulin peak in the NPH profile. Currently, the best basal insulin action can be achieved by using insulin detemir or insulin aspart/lispro as a constant infusion in an insulin pump.

Short-acting insulin

Regular human insulin is inferior to the rapid-acting insulin analogues as its action is too slow to control the peak postprandial glucose and the risk of late postprandial hypoglycemia is increased. This mismatch between insulin to meal can be ameliorated by prescribing a very low carbohydrate meal and a large, between-meal, snack.

Rapid-acting insulin analogues

The rapid-acting insulins lispro and aspart have greater postprandial control, reduced hypoglycemia and greater convenience of administration then regular insulin. Insulin glulisine has not been studied in pregnancy.

Insulin lispro has a rapid onset (10–30 min) and a shorter duration of action (3–5 h) in comparison to human insulin. Studies have suggested several advantages of lispro compared to regular insulin: (a) improves postprandial glycemia in women with GDM [36]; (b) neonates of mothers on lispro displayed lower cranial/thoracic circumferences averaging 10th to 25th percentiles [36]; (c) lowers predelivery HbA1c in women with GDM [37]; (d) unlikely to cross the placenta [38].

In contrast, other reports suggested congenital anomalies with the use of lispro [39]. However, this association is probably due to poor glycemic control rather than drug-induced teratogenesis [40].

Insulin aspart also has faster absorption compared to regular human insulin. A study of aspart versus human insulin in T1 diabetic pregnant women demonstrated greater postprandial control, less nocturnal hypoglycemia, and reduced fetal loss and preterm deliveries [41,42].

Safety of insulin analogues

A concern for the use of insulin and its analogues was raised regarding their mitogenic effects. Insulin-like growth factor-1 receptor (IGF-1R) is a protein structurally similar to the insulin receptor. The individual level of IGF-1R of each cell was found to have an important role in the ability of insulin to promote growth. Insulin aspart and detemir exhibited 18% and 84% decrease in IGF-1 affinity, respectively, compared to human insulin [43]. In contrast, lispro and glargine had elevated affinities of 1.5- and 6.5-fold, respectively, compared to human insulin. Thus, mitogenic potential of glargine should be further studied.

Oral antidiabetic agents

Glyburide transfers minimally the placenta. Even after it crosses the placenta, glyburide may be actively effluxed from the fetus to the mother [44]. In studies by Langer et al., no association has been established between maternal glyburide use and macrosomia, neonatal hypoglycemia, other neonatal morbidities, or cord serum insulin concentration [45,46].

Metformin has been shown to cross the placenta [47]. It was used in several states: (a) To increase fertility and reduce spontaneous abortions in nondiabetic women with polycystic ovarian syndrome. In these women, metformin was not associated with teratogenesis and adverse growth, motor and social development at 3- and 6-month follow-ups [48,49]. (b) To control non-insulin-dependent diabetes in the first trimester. It has been shown to be relatively safe and with no increased risk in congenital anomalies. (c) To control GDM during the second and third trimester of GDM. No adverse perinatal outcomes were observed when compared to insulin treatment [50,51].

Overall, the complete safety and efficacy of oral antidiabetic agents in pregnancy cannot yet be conclusive. Metformin has less utility as a prospective monotherapy than glyburide since fewer women on the latter therapy require supplement insulin to maintain glycemic control. Taken together, insulin therapy with intermediate/long and rapid-acting profiles is strongly recommended

for the treatment of diabetes during pregnancy. When pharmacologic treatment is required in patients with pregestational diabetes, insulin should be used exclusively.

New technologies

Continuous subcutaneous insulin infusion (CSII) (insulin pump)

CSII is an alternative treatment to multiple daily injections (MDI) for people with T1DM. The new and modern pumps are smaller, more efficacious, easier to use and safe. However, no clear difference between CSII and MDI has been established for treatment in pregnant women with T1DM. Rather, both treatments are safe and valid during pregnancy [52]. Nevertheless, CSII treatment improves patients' satisfaction and lifestyle flexibility compared to MDI.

Continuous glucose monitoring system (CGMS)

As previously mentioned, CGMS use during the second half of pregnancy enabled the definition of normal glycemia. Next, the time interval from meal to peak postprandial glucose levels was evaluated. Whereas in nondiabetic pregnancy the interval was 70 min, it was somewhat later, ~90 min, in gestations complicated by diabetes [2,53]. In addition, the peak glucose values were $103 \pm 26\,\mathrm{mg\,dL^{-1}}$ and $164 \pm 53\,\mathrm{mg\,dL^{-1}}$ in patients with well-controlled and poor-controlled diabetes, respectively. Taking into account the glycemic targets currently recommended for diabetes in pregnancy ($140\,\mathrm{mg\,dL^{-1}}$ at 1 h and $120\,\mathrm{mg\,dL^{-1}}$ at 2 h, Table 56.8), it was suggested by Chitayat et al. [40] that blood glucose determinations should be taken at 90 min postmeal with a desired glucose value of ~$110\,\mathrm{mg\,dL^{-1}}$. Importantly, this suggested glucose target should be further tested for its correlation to pregnancy outcomes.

CGM was studied for several aspects of diabetes treatment in pregnancy. First, using CGM for treatment assessment, it was shown that undetected hyperglycemia and asymptomatic hypoglycemic events are common during pharmacologic treatment in GDM [54,55]. Second, "blinded" CGM for 72 hours was used for adjustment of therapy in pregnant women with T1DM [56]. It was concluded that this CGM method is not advisable as there is a wide variability in the day-to-day glucose levels of T1DM pregnancies. Hence, real-time CGM use could possibly overcome this limitation. Consequently, a study was designed with a sample size large enough to provide data on pregnancy outcome in T1DM using real-time CGM. This CONCEPT study in pregnant women or women planning pregnancy has already been launched in 2013.

Future technological development consists of an artificial pancreas, based on a "closed-loop" system, i.e. delivering insulin and/or glucagon/glucose, sensing glucose and controlling delivery according to blood glucose levels [40]. However, the accuracy of the current CGM and algorithms is not yet sufficient to permit the loop to be closed. Thus, research direction should include the improvement of CGM and insulin algorithms. Implementation of an artificial pancreas for diabetes in pregnancy will hopefully lead to a perinatal outcome similar to nondiabetic subjects.

Special considerations during pregnancy, labor, and delivery

Fetal assessment

There are some important considerations for fetal assessment, during prenatal follow-up:

1 Determination of gestational age: As for any pregnancy, especially those complicated by diabetes, women should undergo a sonographic evaluation during early first trimester. The purpose is confirmation of viability, due to the higher risk of fetal loss, and accurate validation or determination of gestational age, because of possible emergence of fetal growth abnormalities later in pregnancy, and the goal of term delivery [57].

2 Detection of congenital anomalies: It is of importance and should be initiated as early as the first trimester and repeated in the second trimester of pregnancy. There is a considerable controversy regarding the optimal time at which to perform the sonographic examination aimed to detect structural anomalies. The NICE antenatal care guidelines recommend that ultrasound screening for fetal anomalies should be routinely offered, between 18 to 21 weeks [57]. Others recommend performing two anomaly scans: the first at 10–14 weeks of gestation and the second at 20–22 weeks.

3 Fetal well-being: There are two main tests used in modern obstetrics to assess and monitor fetal well-being: fetal cardiotocography (using the nonstress test, NST) and the biophysical profile (BPP). The application of these tests and the reassurance they provide may prevent unnecessary early interventions and allow prolongation of pregnancy to term. The ACOG recommends that antenatal testing be performed on all those with poor glycemic control or any other related pregnancy complications [9]. The method of testing (NST or BPP) is left to the discretion of the provider guided by local practice. There is no unified opinion regarding the need for antepartum fetal assessment in women who have well-controlled, uncomplicated, preexisting or gestational diabetes. There is also no consensus on the appropriate timing to initiate testing, and the intervals to do so. It is usually started at 32–34 weeks on a weekly basis, but testing at earlier gestational ages and in shorter intervals, may be warranted in some pregnancies complicated by additional high-risk conditions.

4 Surveillance of fetal growth: It is important to detect cases in which fetal growth is deviant: either small or large for gestational age. Estimated fetal weight (EFW) employing various formulas is the most commonly used method. Although the accuracy of fetal weight estimation decreases with increasing

birth weight there is no significant difference in the absolute error of birth weight in infants born to diabetic mothers and those born to women without diabetes, at about 10%.

Abdominal circumference (AC) is another method to estimate fetal growth, for the evaluation of metabolic control as well as the risk for macrosomia and shoulder dystocia. No difference was found between accuracy of EFW and that of abdominal circumference [58]. AC measurements combined with serial measurement of maternal blood glucose levels are a good indication of metabolic control and help modify treatment. Women with fetal AC > 75th percentile should be offered a tighter regime for glycemic control. Another form of deviant fetal growth is fetal growth restriction, usually defined as birth weight lower than the 10th percentile for a given gestational age and sex. Growth restriction is not a common complication of diabetic pregnancies and is more likely to occur in pregnancies of diabetic women suffering from severe vasculopathy.

Timing of delivery

The decision to deliver a patient with diabetes depends on a balance between potential complications of stillbirth, macrosomia, and shoulder dystocia against the risk of premature delivery as well as potential complications of labor induction. A summary of a decision analysis for timing and mode of delivery in pregnancies complicated by diabetes is presented in Figure 56.2. Maternal metabolic control, gestational age, and fetal growth assessment are all factors that should be considered. As a general rule, labor and vaginal delivery are aimed to occur spontaneously at term, after fetal maturation is achieved, provided that the patient's diabetes is well controlled and antepartum surveillance is normal. Fetal indications favoring a planned delivery include macrosomia, LGA, previous stillbirth as well as prevention of stillbirth and reduction in shoulder dystocia. Maternal indications for a planned delivery include hypertension, diabetic vasculopathy, and poor compliance with the diabetic management resulting in adverse glycemic control.

In patients who fail to meet targeted glycemic control levels, normal fetal surveillance tests and no other immediate/emergent indication for delivery, a positive lung maturation test should precede the decision to deliver. If test results are negative, patients should be managed expectantly with fetal surveillance tests and lung maturation test repeated in a week. When diabetes is well controlled and gestational age is well documented, RDS at or beyond 39 weeks of gestation is rare enough that routine amniocentesis for pulmonary maturity is not necessary.

Mode of delivery

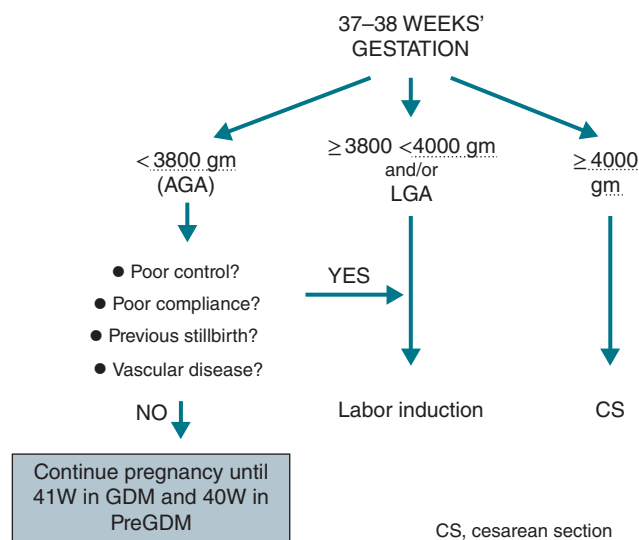
The optimal mode of delivery for a diabetic mother remains undecided. High rates of shoulder dystocia and Erb's palsy have prompted adoption of early induction to achieve vaginal delivery or a primary cesarean section in selected patients, based on estimated fetal size. Such approaches are limited by the relative inaccuracy of ultrasound prediction of birth weight,


Figure 56.2 Decision analysis for timing and mode of delivery in pregnancies complicated by diabetes.

and by the high number needed to treat in order to prevent a single adverse outcome.

Cesarean delivery to prevent traumatic birth injury may be considered, as avoiding vaginal delivery when macrosomia is suspected reduces the rate of shoulder dystocia, Erb's palsy, or brachial plexus injury. Rouse et al. [59] calculated the probability of shoulder dystocia based on birth weight in diabetic and nondiabetic pregnancies. For birth weights of 4500 g or more there was a 52% probability in diabetic compared to 14% in nondiabetic pregnancies, and the mean probability that a neonatal brachial plexus injury would persist was 6.7 % (range 0 – 19%). Thus, to prevent one case of permanent brachial plexus injury in babies weighing 4500 g or more would necessitate 153 cesarean deliveries in diabetic mothers and 419 in nondiabetic mothers. If a cut-off of 4000 g is used, then 169 cesarean sections would be required in diabetic women compared to 654 in nondiabetic women. Conway et al. [60] conducted elective cesarean delivery in EFW > 4250 g and offered induction of labor if EFW was lower. Shoulder dystocia was reduced from 2.8% to 1.5% (OR 0.5 range 0.3 – 1.0). The cesarean delivery rate has increased from 21.7% to 25.1%. The ACOG recommends that an EFW > 4500 g is an indication for cesarean delivery.

The Cochrane database [61] compared a policy of elective induction at 38 weeks to expectant management up to 42 weeks. There was no difference in cesarean delivery rates between the groups (RR = 0.81; 95% CI 0.52 – 1.26), the induction group had a lower risk of macrosomia (RR = 0.56; 95% CI 0.32 – 0.98) and there were three cases of mild shoulder dystocia in the expectant management group. A large retrospective cohort study [62] conducted in the USA encompassing data for more than 100,000 deliveries found that although women with diabetes had an increased risk of cesarean delivery compared to women without diabetes (OR 2.00; 95% CI 1.83 – 2.19), induction of labor was associated with a lower risk of cesarean delivery

compared to those whose labor was not induced (OR = 0.77; 95% CI 0.5–0.89). Kjos et al. demonstrated that induction at 38 weeks in a population of women with GDM was associated with a lower frequency of LGA and shoulder dystocia without an increased rate of cesarean delivery [63]. This is in contrast to studies of induction in nondiabetic women in which suspected macrosomia is apparently associated with an increased rate of cesarean delivery.

Glycemic control during labor

Neonatal hypoglycemia develops due to fetal hyperinsulinemia. Following birth, in the absence of continuous exposure to sufficient levels of glucose, the newborn may become hypoglycemic. Several trials have demonstrated that maternal hyperglycemia during labor and delivery is associated with neonatal hypoglycemia [64], birth asphyxia, and nonreassuring fetal heart rate tracings. Targeting maternal glucose levels to values of 4–7 mmol L^{-1} (72–126 mg dL^{-1}) during labor, leads to a lower risk of maternal hypoglycemia than targeting lower levels.

Postpartum care of women with diabetes

Women with gestational diabetes mellitus, even after delivery, remain a high-risk group for the development of impaired fasting glucose, impaired glucose tolerance, diabetes mellitus (mostly type 2, but to a lesser extent even type 1), and the full spectrum of the metabolic syndrome. The onset of postpartum T2DM is observed within 5–10 years. The rate is reported from 2.6–70%, from 6 weeks to 28 years postpartum [65]. A multitude of studies reported various risk factors that may predict postpartum diabetes, including: ethnicity, fasting glucose values at OGTT and during pregnancy, postpartum fasting glucose, insulin use during pregnancy, maternal age, weight, BMI, HbA1c, previous history of gestational diabetes, family history of diabetes and parity [65,66]. Fasting glucose alone may not identify all women with glucose intolerance, and a formal glucose tolerance test is needed by a 75-g OGTT 6–12 weeks after delivery, and may be repeated periodically. Recurrence rates for gestational diabetes are 30–84%. Therefore, women with previous GDM, planning future pregnancies should be consulted appropriately prior to their following pregnancy.

Breastfeeding

All women with GDM or overt diabetes should be encouraged to breastfeed. Breastfeeding has been shown as a protective factor for the occurrence of fetal and maternal complications, and may reduce childhood obesity and T2DM. Also, breastfeeding may have maternal advantages, and postpartum lactation may be associated with lower glucose levels, weight loss, and lower rates of T2DM.

Postpartum contraception

Using combined oral contraception in T1DM does not influence glycemic control or promote end organ damage. Women with a history of gestational diabetes mellitus show no increase in the risk for T2DM, when taking the pill. Studies of the contraceptive patch and vaginal ring show that their metabolic effects are similar to those of the oral contraceptives, and they may be assumed safe for women with previous gestational diabetes. Copper IUD safety was demonstrated for healthy, T1 and T2DM women. The levonorgestrel-releasing IUD was studied in healthy and T1DM women and was not associated with metabolic disturbances. The data on the effect of progestin-only contraceptive is controversial, as some suggested an increased risk for T2DM in breastfeeding women with prior gestational diabetes, while others have not shown an effect on glucose values.

Key points

- Aging is a major driver of the diabetes pandemic in addition to other risk factors, such as obesity and reduced physical activity.

- The growing impact of the diabetes epidemic in elderly populations affects both developed and developing countries.

- Diabetes in older adults is associated with higher mortality, reduced functional status, increased risk of institutionalization, as well as an enormous human and economic burden.

- Several conditions known as geriatric syndromes are common in older adults with diabetes and may have an impact on management and quality of life.

- The projected increase in diabetes prevalence in the elderly warrants more research and better healthcare planning to prevent complications, preserve functionality, and promote better quality of life.

Diabetes epidemiology in older adults

There are growing proportions of older adults among those with diabetes worldwide. Based on the 2012 International Diabetes Federation (IDF) *Diabetes Atlas*, it is estimated that 34.5% of the overall population with diabetes in 2012 were aged 60–79 years [1]. This proportion is expected to reach 41% by year 2030 and more than 252 million older adults with diabetes by 2035, according to estimates from the 2013 IDF *Diabetes Atlas*. The IDF regions and countries with the largest projected increase in the proportion of elderly patients with diabetes by 2030 are: Western Pacific (China and Indonesia), South & Central America (Colombia and Brazil), North America & Caribbean (Mexico, Canada, and USA), and Southeast Asia (Sri Lanka, Bangladesh, and India) (Table 57.1). Projections in the US suggest that the number of cases of diagnosed diabetes in those over 65 years of age will increase by 4.5-fold between 2005 and 2050 [2].

Data from the 2013 IDF *Diabetes Atlas* also showed near 135 million elderly patients with diabetes worldwide (with an overall prevalence of 18.6%). The countries with the largest number of older adults with diabetes were China (~33 million people, 20.6% prevalence), India (~15 million people, 16.2% prevalence), and the US (~10 million people, 21% prevalence), although data from the Centers for Disease Control and Prevention (CDC) has estimated than more than 25% of the population aged 65 years and older has diabetes in the US [3]. Population-based data in Western Europe showed approximately 25% diabetes prevalence in the age group 70–79 years [4]. However, the countries with the largest prevalence of diabetes in the elderly in 2012 were Egypt (32.9%), Mexico (29.6%), and Brazil (27.8%).

The prevalence of diabetes among elderly patients also varies depending on the diagnostic criterion used. Postprandial hyperglycemia, likely related to physiologic reductions in insulin secretion with aging [5,6], is a prominent characteristic of type 2 diabetes (T2DM) in older adults [7]. Using the A1c or FPG diagnostic criteria, as it is currently done for national surveillance, one third of older adults with diabetes are undiagnosed in the US [3]. Reports in Europe have supported the value of adding 2-hour glucose measurements (post glucose load) to identify incident diabetes in older populations [8].

Table 57.1 Top 10 countries with the greatest increase in number of older people with diabetes by 2030 [1]

	Country/ territory	2012		2013	2030		2012–2030
		No. of people with diabetes (60–79) in 1000s	% of elderly among adults with diabetes	No. of people with diabetes (60–79) in 1000s	No. of people with diabetes (60–79) in 1000s	% of elderly among adults with diabetes	Projected increase in people with diabetes (60–79) in 1000s
	World	128,167.0	34.5	134,614.0	226,054.2	41.0	97,887.2

Source: Florez 2013 [1].

Aging of the overall population is acknowledged as one driver of the diabetes epidemic [9] but other risk factors such as obesity, reduced physical activity, low education, smoking, dyslipidemia, and hypertension have been reported across different populations [8,10–13]. Similarly the prevalence of prediabetes (impaired glucose regulation) increased with age, reaching up to 25% (men) and 30% (women) above 70 years of age [4].

Diabetes in older adults is associated with higher mortality, reduced functional status, increased risk of institutionalization, as well as an enormous human and economic burden [14]. There is also substantial risk for both macrovascular and microvascular complications associated with diabetes in the elderly. Major lower extremity amputations [15], myocardial infarction, visual impairment, and end-stage renal disease have higher rates in the elderly, particularly in those aged 75 years and older, than in any other age group. Although death rates related to hyperglycemic crisis have declined markedly in the past two decades, they are still higher in older adults with diabetes. In contrast there is a growing concern, particularly in those aged 75 years and older, with increasing rates of emergency department visits related to hypoglycemia [16].

Older adults with diabetes may either have incident disease or long-standing diabetes with onset in middle age or earlier. Demographic and clinical characteristics of these two groups differ in a number of ways, adding to the complexity of making generalized treatment recommendations for older patients with diabetes.

Pathophysiology of diabetes in the elderly

Many of the differences between older patients compared to younger patients with diabetes stem from the pathophysiology of aging combined with alteration in glucose metabolism including insulin secretion, insulin resistance, and hepatic

glucose metabolism [17]. In addition, conditions associated with aging such as coexisting illnesses, increased adiposity, decreased physical activity, sarcopenia, and effect of medications used to treat comorbidities further impact abnormal glucose metabolism in the elderly [18].

Metabolic alterations
Abnormal insulin secretion and resistance to insulin action are primary pathophysiologic factors in development of diabetes in older adults. The abnormality in insulin secretion is related to alterations in insulin release, loss of pulsatility, loss of first-phase insulin secretion, and decreased response to incretin hormones with aging [19]. Abnormal insulin sensitivity is commonly seen with aging and is exacerbated by confounding factors such as higher body fat content and loss of fat-free mass [20]. Recent studies have shown that lean and obese older adults with diabetes have distinct metabolic profiles [21]. Compared to young adults, obese older people with diabetes have relatively normal insulin secretion, but marked resistance to insulin-mediated glucose disposal. On the other hand, lean older people with diabetes have profound impairment in glucose-induced insulin secretion, but minimal resistance to insulin action [21,22]. The older adult with diabetes also shows normal fasting hepatic glucose production compared to elevated hepatic glucose production in younger patients [22].

Environmental impact
Impact of diet and exercise is similar in older and younger populations. A highly processed, low-fiber, high-energy diet is linked to higher risk of diabetes at all ages. Aging causes structural and functional changes in skeletal muscles which forms the basis of changes in body composition and metabolic abnormalities such as insulin resistance [23]. Obesity, higher fat to muscle ratio, and lack of physical activity are common with aging and contribute to higher risk of diabetes.

Genetic predisposition

Genetic predisposition magnifies age-related changes in glucose metabolism although the specific genes responsible are not identified yet. A family history of diabetes and certain race and ethnic groups such as African American and Hispanic descent confer higher risk of developing diabetes with aging, supporting the hypothesis of genetic predisposition.

Other factors

A variety of aging-related changes have shown to add to the risk of abnormal glucose metabolism. Autoimmunity has shown to play a role in the impairment of glucose-induced insulin secretion in lean older people with diabetes [17]. Proinflammatory cytokines such as tumor necrosis factor alpha [24] and C-reactive protein [25] have been associated with higher risk of diabetes in elderly patients. On the other hand adiponectin was found to be associated with lower risk of diabetes in older men and women [26]. Age-associated reductions in mitochondrial oxidative and phosphorylation activity have also been shown to contribute to insulin resistance in the elderly [27]. Low levels of testosterone in men and higher levels of testosterone in women are associated with higher risk of insulin resistance and diabetes in the elderly [28].

Effect on clinical presentation

The unique pathophysiology of diabetes manifests as a unique clinical presentation of the disease in the older population. The renal threshold for glucose increases with age, leading to higher blood glucose level before glycosuria is detected [18]. As a result, urine dipsticks are less likely to detect abnormality and polyuria may not be a prominent symptom. Furthermore, polydipsia may be absent because of impaired thirst mechanisms in older adults which also lead to dehydration. Thus, the classic symptoms of hyperglycemia—polyuria and polydipsia—are often not present. As a result, clinical presentation of diabetes is altered in older adults and may manifest as infections or failure to thrive leading to serious complications such as nonketotic hyperosmolar coma [29].

Prevention and management of diabetes and its comorbidities in older adults

Screening

Older adults are at high risk for both diabetes and prediabetes. Surveillance data in the US suggest that nearly half of older adults may have prediabetes [3] while data in Europe suggest that up to one third may be affected [4]. Screening for diabetes and prediabetes in older subjects should be in accordance with accepted guidelines but no age-modified criteria are currently recognized [30]. The American Diabetes Association recommends using either fasting plasma glucose, hemoglobin A1c, or oral glucose tolerance test (OGTT) [31].

In high-risk older subjects with a normal fasting glucose, and where an OGTT is not feasible, determination of HbA1c may be helpful [30]. The benefits of identification of prediabetes and asymptomatic diabetes in older adults depend on whether primary or secondary preventive interventions would likely be effective, and on the anticipated time frame of benefit of interventions weighted against the patient's life expectancy [32].

Prevention of type 2 diabetes

Numerous clinical trials have shown that in high-risk subjects (particularly those with impaired glucose tolerance or IGT), the incidence of T2DM can be prevented or delayed by lifestyle interventions or by various classes of medications which have been reviewed elsewhere [33]. The Da Qing Study (China) randomly allocated 33 clinics (557 persons with IGT) to 1 of 4 study conditions: control, diet, exercise, or diet plus exercise [34]. Compared with the control group, the incidence of diabetes was reduced in the three intervention groups by 31%, 46%, and 42%, respectively and with a modest weight loss in study participants. The Finnish Diabetes Prevention Study evaluated 522 obese persons with IGT randomly allocated on an individual basis to a control group or a lifestyle intervention group that emphasized physical activity, weight loss, limited total dietary intake and intake of saturated fat, and increased intake of dietary fiber [35]. During the trial, the incidence of diabetes was reduced by 58% in the lifestyle group compared with the control group. The U.S. Diabetes Prevention Program is the largest trial of primary prevention of diabetes to date and was conducted at 27 clinical centers with 3234 overweight and obese participants with IGT randomly allocated to 1 of 3 study conditions: control, use of metformin, or intensive lifestyle intervention [36]. The goal of lifestyle intervention was to achieve and maintain 7% or greater weight loss through a low-calorie, low-fat diet and 150 or more minutes of moderate physical activity weekly. Nearly 20% of study participants were age 60 years and older at enrollment. Overall, in 3 years the incidence of diabetes was reduced by 31% in the metformin group and 58% in the lifestyle group. Older adults had a greater benefit (71% reduction) with lifestyle intervention but did not appear to benefit from metformin [36,37]. Additional benefits of the lifestyle intervention that might impact older adults have been reported, including reduction in urinary incontinence [38], reduction in cardiovascular risk factors [33], and improvement in several quality-of-life domains [39]. Although these results suggest that diabetes prevention through lifestyle intervention may be pursued in relatively healthy older adults, the DPP did not enroll a significant number of study participants over the age of 70 years or those with functional or cognitive impairments. Preventive strategies that can be efficiently implemented in clinical settings and in the community have been developed and evaluated [40], but as yet there has been little focus on older adults in these translational studies.

Challenges and management principles

Care for elderly patients with diabetes poses a unique clinical challenge [41]. The management of older patients with diabetes is complicated by the medical and functional heterogeneity of this group [17,42]. The heterogeneity of this population is a key consideration for clinicians developing intervention strategies and establishing targets for elderly patients with diabetes [30,32,43]. Clinical and functional heterogeneity include:

- Older adults who have just converted from prediabetes to diabetes, have a few comorbidities but no chronic complications and remain active with excellent functional status;
- Patients whose diabetes was recently diagnosed but have had significant hyperglycemia for many years and already have complications successfully compensated to preserve functionality;
- Elderly patients who have developed diabetes in middle age and developed over time multiple related comorbidities and complications, which have been partially compensated;
- Patients who are frail and even disable, with advanced cognitive impairment, multiple comorbidities and complications.

Since many older adults with diabetes are in-between the afore-mentioned stages, with mild or early functional limitations and multiple risks for worsening morbidity, they require an individualized plan based on their functional status and life expectancy [30,43,44]. Specific data on the treatment options for glycemic, lipid, and blood pressure control have been recently reviewed [32] and a framework for considering treatment goals in older adults was proposed. This framework is an attempt to balance the expected time frame of benefit of interventions with anticipated life expectancy [45,46]. Three major classes of older patients with diabetes and increasing levels of mortality risk were identified: (1) those who are relatively healthy, (2) those with complex medical histories where self-care may be difficult, and (3) those with a very significant comorbid illness and functional impairment [32].

The goal of physicians and other providers caring for elderly patients with diabetes should be to optimize glycemic control and reduce associated cardiovascular risk factors in an effort to maximize long-term quality of life [32,43,47]. On the other hand, for frail older patients, particularly those with severe comorbidities and disabilities, aggressive management is not likely to provide benefit and may even result in harm, as a consequence of frequent hypoglycemia associated with aggressive glycemic control [48,49]. Several drug therapy options alone and in combination are available for treatment of diabetes in the elderly [50]. At first glance, the therapeutic principles for glycemic control in elderly patients with diabetes are not very different from those in younger adults. However, the elderly with diabetes require additional areas of consideration in goal setting and use of treatment modalities. Treatment goals must be individualized, and at times the enthusiasm for tight glucose control may need to be weighed against safety concerns. In deciding the best strategy for the intervention, it is important to adjust the regimen and goals periodically as the diabetes progresses, complications develop and/or functionality may decline. In these patients, the regimens should be simplified with less frequent dosing, avoiding interaction with other drugs that may affect the treatment effectiveness. The presence of renal, liver and/or cardiovascular comorbidities may create contraindications and/or increase the risk of hypoglycemia. Other important considerations are cost and the effect of these medications on weight and/or lipids. In general, oral agents should be started at the lowest possible effective dose to minimize the risk of adverse events.

Geriatric syndromes in older adults with diabetes

As individuals age, they have a higher likelihood of developing multiple medical conditions, and with each of these conditions comes the probability that they will need to take multiple daily medications. In the past, the significant health burden in older people with diabetes was attributed primarily to higher risk of macrovascular and microvascular complications. However, many coexisting medical conditions (such as cognitive dysfunction, depression, functional disability, falls, polypharmacy, urinary incontinence, and chronic pain) not typically associated with diabetes occur at higher frequency in older adults with diabetes [32]. These conditions, termed geriatric syndromes, may interfere with a patient's ability to perform self-care tasks, including glucose monitoring, understanding role of diet and exercise in glucose excursions, and following a complex insulin regimen. Difficulty with self-management may lead to increased risk of nonadherence or treatment errors, contributing to an increased risk of hypoglycemia and poor glycemic control, which in turn leads to further difficulty with self-management and ultimately increased risk of morbidity and mortality. Figure 57.1 shows the complex interaction seen in older patient with diabetes. Thus, before developing treatment and management plans for older adults, it is of key importance to conduct a careful and comprehensive assessment for all potential comorbidities, which will very possibly impact how you plan your therapeutic approach.

Cognitive impairment

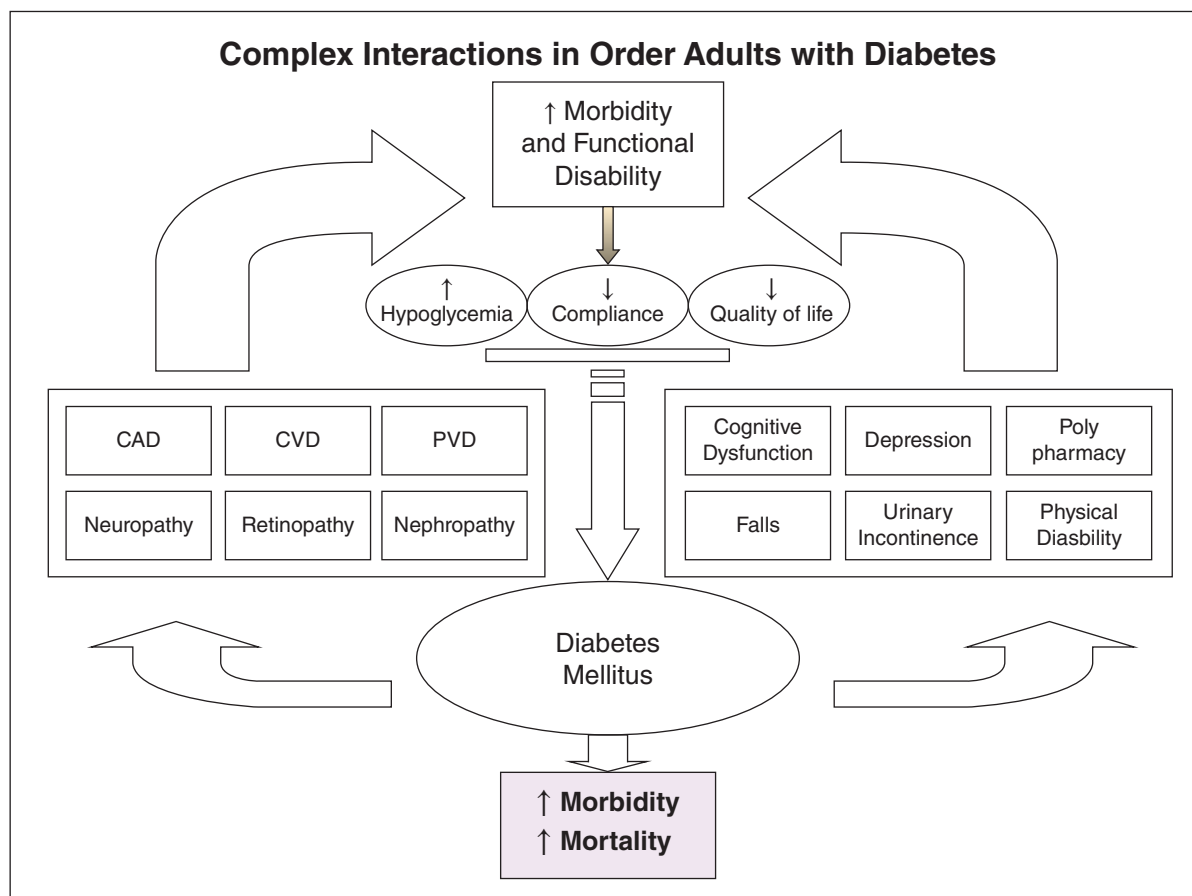
Diabetes is associated with 1.5-fold greater risk of cognitive decline and 1.6-fold increased risk of future dementia [51]. Cognitive dysfunction in older adults with diabetes may manifest as deficits in psychomotor efficiency, global cognition, episodic memory, semantic memory, and working memory [52]. In particular, executive functioning which is mediated by the frontal lobe, affects behaviors such as problem solving, planning, organization, insight, reasoning, and attention. Many elderly patients with cognitive dysfunction remain undiagnosed; particularly in the early stages as subtle declines in cognitive function remain unrecognized by family as well


Figure 57.1 Interaction of diabetes with comorbid conditions in older adults. On the left side, both macrovascular and microvascular chronic complications contribute to further morbidity and disability. On the right side, geriatric syndromes also contribute to further reduction in quality of life and higher risk of morbidity and mortality. CAD, coronary artery disease; CVD, cerebrovascular disease; PVD, peripheral vascular disease.

as healthcare providers. Cognitive dysfunction can interfere with self-care abilities such as following medical, nutritional, and exercise regimens, leading to increased risk of treatment complications. In a small study examining patients with diabetes over the age of 70 years, executive dysfunction was identified in more than one third of patients and was associated with poor glycemic control [53]. In clinical practice, short screening tools such as a clock drawing test are useful to assess executive function. An important aspect of recognizing cognitive dysfunction is to realize that these people may not recognize hypoglycemic episodes, may not be able to treat them appropriately, and may forget to report them to providers. Thus they are at high risk of frequent unrecognized hypoglycemic episodes. It is important to provide diabetes education to family members or other caregivers to ensure the safety of the patient.

Depression

Depression is approximately twice as common in people with diabetes compared to the general population [54]. Diabetes and depression have a bidirectional relationship of increased

risk [55]. Meta-analyses have demonstrated that diabetes doubles the risk of depression and that depression is associated with poor glycemic control [56]. Presence of depression is associated with poor adherence to medication and diet regimens, a reduction in quality of life, and an increase in healthcare expenditures [54,57]. A combination of diabetes and major depression leads to higher odds of functional disability compared to either diabetes or depression alone [58]. Depression is frequently undiagnosed and remains untreated in this high-risk population. Timely identification and treatment of depression may increase adherence and improve glycemic control along with overall quality of life for older adults.

Polypharmacy

This is a complex, challenging aspect of caring for elderly adults who often require multiple medications to optimally manage their diabetes and associated conditions [59]. Although, multiple medications are unavoidable in many, careful attention to appropriate dosing, avoidance of drug–drug interactions, interventions to increase regimen adherence, and assessment of financial feasibility are important. In order to treat more

effectively, it is important to keep the medication list current and review it at each medical visit.

Physical disability and falls

Older adults with diabetes have a reduction in physical function and overall health status compared to age-matched controls, and are more likely to use a mobility aid such as a cane or a walker [60]. In a large epidemiologic study, the incidence of disability, defined as onset of inability to do one or more functional tasks (walking 0.25 mile, climbing 10 steps, performing household chores, shopping, and cooking meals) was about twice as high for women with diabetes as those without [61]. Individuals with these disabilities may require assistance from other caregivers or family members to implement tasks such as self-monitoring of blood glucose (SMBG), giving insulin injections, meal preparation, and following a physical activity regimen. Falls, especially the ones resulting in injury, are also more common in older adults with diabetes [62,63]. The increased risk of falls in this population is multifactorial. Presence of peripheral and/or autonomic neuropathy, cardio-vascular disease, reduced renal function, muscle weakness, lower limb dysfunction, functional disability, loss of vision, polypharmacy, and comorbidities like osteoarthritis may contribute to, and worsen the impact of, falls in frail older adults [64]. While good glycemic control prevents progression of some diabetes complications and therefore may decrease the risk of falls, hypoglycemia that occurs as a result of tight glycemic control may increase the risk of falls, underscoring the need for a balanced approach in older adults [65]. People who develop a fear of falling are usually reluctant to follow physical activity recommendations. Referral to an exercise physiologist and a supervised program for physical activity may help such people reduce their fear of falling, and thus lead to increased physical training and lower risk of falls.

Urinary incontinence

Diabetes is associated with higher risk of developing urinary incontinence. This condition in older patients with diabetes, especially women, is also multifactorial in etiology. Risk factors include urinary tract infection, vaginal infection, and auto-nomic neuropathy (resulting in either neurogenic bladder or fecal impaction) [29]. These conditions can be exacerbated by uncontrolled diabetes causing polyuria. Urinary incontinence frequently remains undiagnosed because women do not volunteer the information. Although there is no direct evidence to suggest deleterious effect of incontinence on diabetes control, identification and treatment are recommended to improve quality of life in women.

Chronic pain

Pain is considered the 5th vital sign and should be evaluated at each visit. Many older adults are reluctant to complain about pain. However, pain can increase depression and impair ability to perform self-care and exercise. Pain management may improve overall quality of life in addition to diabetes care.

Diabetes education, self-management, and decision support in the elderly

Diabetes self-management

Self-management relates to tasks that an individual must undertake to live well with one or more chronic condition [66]. It is based on the theory that greater patient confidence in his/her capacity to make life-improving changes yields better clinical outcomes. The goal of self-management education is to increase self-efficacy and improve clinical outcomes by increasing patients' confidence in medical management, coping skills, and skills for health and wellness [66]. The rationale for chronic disease self-management programs is to ultimately change a patient's behavior by increasing the patient's self-efficacy and condition-specific knowledge [67]. Studies targeting self-management in diabetes mellitus have found it to be effective. A study of a self-management program for Spanish-speaking diabetics demonstrated significant improvements over usual care in HbA1c, symptoms, health status, and self-efficacy at 6 months with improvements persisting at 18 months [68]. A similar community-based self-management program showed improvements in health behavior, self-efficacy, and health status among Hispanic older diabetics at 4 months and 1 year [69]. A community-based self-management program intervention failed to show any improvements in HbA1c or healthcare utilization in diabetics over usual care. There were, however, significant improvements in patient activation, self-efficacy, hypoglycemia, depression, communication with physicians, and adherence to healthy behaviors [70].

Internet-based self-management interventions

In recent years these interventions have become widely available. These programs offer patients the freedom to use them at their own pace, and in the comfort of their homes instead of at doctors' offices or at other healthcare institutions. This may represent a significant advantage for older adults, including those who are unwilling or unable to go to healthcare facilities due to mobility impairment or problems with transportation. A few studies have explored the use of Internet-based learning for healthcare of older adults. An Internet-based intervention to improve self-management behaviors and self-efficacy in older adults with diabetes mellitus through synchronous communication (instant messaging and chat) and asynchronous communication (email and a bulletin board) was effective in improving HbA1c levels after 6 months [71]. A large controlled trial randomized 761 diabetic participants to an Internet-based self-management program, and the same program with email follow-up reinforcement and usual care. Individuals in the two treatment groups demonstrated significant improvements in HbA1c, patient activation and self-efficacy at 6 months. The addition of email

reinforcement did not show an effect [72]. Most recently, online personal health records have emerged as a type of Electronic Health Record (EHR) tool, intended to increase patients' access to and ownership over their healthcare information. Patients may be able to use an online personal health record as a means of providing self-management training and education [73].

Clinical decision support in elderly diabetes care

These are rule-based systems that provide information about drug interactions, drug-allergy problems, treatment algorithms, information about alternative medication regimens, and computer-based clinical pathways, or may have more advanced scoring and expert systems that assist clinicians by providing reliable and objective estimation of disease prognoses, probability of adverse events and outcomes [74]. Four features of clinical decision support systems are independent predictors of improved clinical practice: automatic provision of decision support as part of clinician workflow, provision of recommendations rather than just assessments, provision of decision support at the point of care, and computer-based decision support [75]. Evidence regarding the effects of clinical decision support comes from systematic reviews in varied clinical settings. A systematic review included seven randomized controlled trials comparing the effect of computerized clinical decision support versus usual care on diabetes processes of care and clinical outcomes. Five of the seven trials demonstrated significant improvements in clinicians' performance on eye, foot, urine protein, blood pressure, and cholesterol examinations as a result of the intervention. Three out of the seven trials evaluating clinical outcomes failed to demonstrate the superiority of the intervention [74]. Most recently, a large controlled trial randomized patients to receiving either computerized clinical decision support or usual care. The intervention group physicians used the decision support system at outpatient visits by their patients with diabetes. As compared to the control group, the intervention group patients had significant improvements in HbA1c, systolic blood pressure control and maintenance of diastolic blood pressure control but no improvement in LDL-cholesterol [76]. A recent review of 33 studies showed the benefits of clinical decision support tools in improving evidence-based processes of diabetes care but a lack of effect on clinical outcomes [77].

Shared decision-making aids

These aids contribute to patient empowerment and better care with potential impact on healthcare outcomes. Despite their availability and demonstrated efficacy, their use is infrequent [78]. As medications are the most common treatment in diabetes mellitus, decisional aids may have a significant impact in the management of these patients. Paper-based decisional aids can enhance clinicians' and patients' discussions relating to diabetes medications during clinical encounters. Use of these decisional aids demonstrated acceptability, increased involvement in decision making and improved medication

knowledge but did not affect adherence [79,80]. Decision aids can also be helpful in presenting risk information to diabetics. The format of presentation of risk information to diabetic patients represents a challenging task that could benefit from the use of shared decision-making aids [81,82]. Presenting cardiovascular risk in time frames shorter than 10 years improved the comprehension of cardiovascular risk and resulted in increased risk perceptions, emotional responses, and intent to change behavior in diabetics [82]. Patients with diabetes found natural frequency formats helpful for the presentation of risk information but most participants preferred graphical presentations in the form of bar charts aids [81]. More research is needed to ascertain the effectiveness, efficiency, and usability of decision aids for patients with diabetes.

Additional recommendations for the management of T2DM in older adults on a global scale were recently released by the IDF [83]. This guideline provides specific recommendations for education and diabetes self-management in older adults, including those who are functionally independent, those who are dependent (specifically addressing frailty and dementia), and end-of- life care.

Psychological problems and management of patients with diabetes mellitus

Alan M. Delamater, Ashley Marchante and Jennifer Hernandez

Department of Pediatrics, University of Miami Miller School of Medicine, Miami, FL, USA

Key points

- Depression is common in patients with diabetes and has been shown to be associated with decreased self-care behaviors and poor glycemic control.
- Anxiety disorders are also common and have been shown to be associated with poor glycemic control.
- Eating disorders are common, especially in young women with diabetes, are persistent, and increase risk for metabolic control problems and microvascular complications.
- Neurocognitive problems can develop over time with history of poor glycemic control.
- Reliable and valid screening instruments with good clinical utility are available to identify patients with psychological problems and can be used in the clinical setting.
- There is some evidence to support the efficacy of psychological interventions incorporating cognitive behavior therapies to address psychological problems in patients with diabetes.
- Adoption of a patient-centered chronic care model of interdisciplinary care is a skillful approach to increase patient empowerment and improve clinical outcomes.

Introduction

This chapter considers psychological problems and their management in adult patients with diabetes. Both type 1 diabetes (T1DM) and type 2 diabetes (T2DM) are considered. The review is not exhaustive but rather focuses on methodologically sound research that examines psychological problems in patients with diabetes. We review selected studies illustrating the main psychological problems affecting adults with T1DM and T2DM, and also refer to recent reviews including meta-analyses. The main psychological issues include depression, anxiety, eating disorders, and compromised neurocognitive function. Within

each, the prevalence, associated factors, and treatment-related issues are considered. The concluding sections discuss future research needs and recommendations for clinical practice.

Depression

Prevalence

Research has shown that adults with diabetes are much more likely to experience depression than adults without diabetes. The rates of depression in adults with both T1DM [1] and T2DM [2] are high in comparison to the general population. Evidence suggests a bidirectional relationship between depression and diabetes, such that the presence of diabetes increases the risk of developing depression and that the presence of depression increases the risk of developing diabetes [3]. Although the literature is unclear about the bidirectional relationship in T1DM, longitudinal research has found that individuals who experience high levels of depressive symptoms are at increased risk for developing T2DM [4]. Researchers suggest two hypotheses for this trend: behaviors associated with depression, such as poor self-care, may lead to obesity and insulin resistance, and biochemical changes in depression or treatment of depression could result in diabetes [3].

Associated factors

Depression in adults is associated with both medical and psychosocial risk factors, including poorer glycemic control [5], medical complications [1,6], lower health-related quality of life (HRQOL) [7], and greater nonadherence to medication [8]. Although research has found an association between diabetes-related depression and glycemic control, the nature of the relationship is still unclear. Some have found that diabetes-related depression is associated with higher glycosylated hemoglobin A1c (A1c) levels over time [5], but this may

only be true for insulin users [6,9]. Depression is also associated with diabetes-related microvascular and macrovascular complications. In a study conducted over a 5-year period with patients who presented with major depression and diabetes, those with major depression had an increased risk of developing advanced microvascular complications, including end-stage renal disease and blindness, and macrovascular complications, such as heart attack or stroke [6]. The results of a recent meta-analysis indicated that depressed patients are 1.76 times more likely to be nonadherent than nondepressed patients with diabetes [8]. Thus, it is especially crucial to address regimen adherence in patients with diabetes who are depressed.

It is also important to consider psychosocial factors that accompany diabetes-related depression, as they may impact health outcomes as well. Researchers have found a strong association between HRQOL and depression in people with diabetes [7]. However, depressive symptoms have only been consistently associated with the mental components of HRQOL domains and less with the physical functioning domains [7]. Therefore, it is important to consider how specific domains of HRQOL vary across different groups of people who show symptoms of depression.

Treatments for depression
Due to the increased risk for poor health outcomes in individuals with comorbid depression and diabetes, it is important to consider diabetes-specific treatments. Evidence-based treatments for depression have been successful within the general population, including psychological interventions, antidepressants, and collaborative care. The results of a recent meta-analysis demonstrated that cognitive-behavioral therapy (CBT) was the most effective psychosocial intervention to decrease depression in patients with T1DM and T2DM; however, these interventions did not reliably result in significant improvements in glycemic control [10]. Future psychosocial interventions should include a self-care component to address glycemic control as part of CBT treatment for individuals with diabetes.

Antidepressants such as SSRIs have been effective in reducing depression in patients with diabetes, with trends towards improved glycemic control [11]. In a recent randomized, placebo-control trial, pharmacologic treatment with sertraline improved both depression and A1c in low-income minority patients with diabetes [12]. Collaborative care, which includes CBT and antidepressants, has been effective in reducing levels of depression. The results of a recent randomized control trial found that, in a sample of patients with depression and T2DM, an integrative care intervention was effective in reducing both A1c levels and depression [13]. This integrative care intervention included individualized programs to improve adherence to antidepressants and treatment adherence. While collaborative care treatment programs show promise for improving depression and glycemic control in adults with diabetes, future research should consider the long-term effectiveness of these interventions.

Anxiety

Prevalence
There is a substantial literature documenting the prevalence and course of both affective and anxiety disorders in adults with diabetes. For example, research findings have demonstrated that generalized anxiety disorder (GAD) is more common in patients with diabetes than in the general population [14]. The results of a meta-analysis indicated that 13.5% of patients with diabetes met criteria for GAD, 40% had elevated symptoms of anxiety, and 26.5% met criteria for having anxiety disorder not otherwise specified [14]. These researchers suggested that the higher rates of GAD may be due to the psychological stress of disease self-management or fears of hypoglycemia and medical complications. An early report indicated rates of disturbance due to depression and anxiety in a clinical sample of adults with diabetes as 41% and 49%, respectively, significantly higher than the 10–20% rates to be expected in the general population [15].

Associated factors
Gender is a significant correlate of both anxiety and depression in patients withT1DM and T2DM, with women exhibiting higher rates than men [15–17], particularly women of lower socioeconomic status [15]. Research also indicates that adults with diabetes who screen positive for anxiety are more likely to have poor glycemic control [15,17–19]. Anxiety is also greater for those patients who have diabetes-related health complications [15]. The results of a study in Ireland of 1456 patients with diabetes revealed 22% screened positive for significant symptoms of anxiety and depression, and those who did were more likely to have diabetes-related health complications, uncertainties about glycemic control, to be female, and to be smokers or have a history of alcohol abuse [17].

Treatments for anxiety
CBT is among the best studied intervention for anxiety disorders in the general population, and is considered to be a well-established treatment for panic disorder, agoraphobia, and GAD. However, there have been relatively few studies addressing the treatment of anxiety disorders in patients with diabetes, although there are some reports of the effects of interventions to reduce stress and improve coping skills.

Due to the possible deleterious effects of stress and anxiety on glycemic control, researchers have studied the effects on glycemic control of stress management including relaxation training in individuals with T2DM, demonstrating significant improvements in A1c over 1 year [20]. Various types of relaxation interventions have also been effective in improving glycemic control of patients with T2DM. For example, a recent study showed improved insulin resistance after a traditional Chinese relaxation exercise (Qigong) [21]. Several studies showed moderate improvements in state and trait anxiety scores for patients trained in relaxation [21–23].

A recent randomized controlled trial examined the effects of a mindfulness-based group intervention program in outpatient with diabetes. Results showed significant reductions in stress, anxiety, and depression, as well as improved HRQOL in patients receiving the intervention; however, there was no impact on A1c [24]. Another randomized controlled study demonstrated that a group CBT intervention for adults resulted in reduced diabetes-related stress and improved coping and A1c, effects which were maintained at 6-month follow-up [25]. A recently reported study indicated that the positive effects of CBT for patients with anxiety and depression may be delivered over the Internet [26]. In this study, patients receiving the web-based intervention had significant reductions in diabetes-related distress and depression, but there were no effects on A1c [26].

Anxious individuals with diabetes may be susceptible to significant fears of hypoglycemia, injections, and/or diabetes-related complications. Research indicates that these fears are associated with poor adherence [27], highlighting the importance of interventions to reduce anxiety symptoms for these patients. There is evidence that for clinically anxious individuals with diabetes, CBT can be effective in reducing panic attacks, avoidance behaviors, and fear of hypoglycemia [28]. It is important to note that pharmacologic intervention including benzodiazepines and SSRIs can be effective in the treatment of anxiety disorders, but have not been well studied in adults with diabetes [29].

Eating disorders

Prevalence

Early studies indicated that eating disorders such as bulimia are common in adults with diabetes, especially among young women with T1DM [30]. Prevalence rates for anorexia, bulimia, binge-eating disorder, and eating disorders NOS have been shown to range from 5.4% to 7% in women with T1DM (lifetime 10.5% to 14.4%) and 6.5% to 9% in women with T2DM (lifetime 10% to 13.7%) [31]. In men and women, the prevalence of co-occurrence of binge-eating disorder and T2DM diabetes ranges from 2.5% to 26% [32,33]. The prevalence of subclinical levels of binge-eating patterns co-occurring with T2DM have been reported from 14% to 40% [34,35].

Rapid weight gain associated with the start of insulin treatment and the emphasis of dietary restrictions in diabetes management may help explain the increased prevalence of eating disorders in young women with T1DM. Moreover, insulin injection omission or under-dosing provides patients with T1DM a unique tool to inappropriately manage weight and therefore may partially explain the increased prevalence [36]. Rates of insulin omission among young adolescent girls with T1DM have been reported in the range of 11–14%, and up to 34% for older adolescents and young adult women [37].

Research indicates that there is a difference in the initiation of eating disorders between people with T1DM and T2DM: individuals with T1DM were more likely to develop an eating disorder after the onset of diabetes, while those with T2DM were more likely to have been diagnosed with binge-eating disorder (BED) above all other eating disorders, and more often, their eating disorder preceded their onset of diabetes [31].

Associated factors

Research has shown that patients with T1DM who have eating disorders and omit insulin are more likely to have poor glycemic control [37,38]. Prospective studies have shown that eating disorders in young women with T1DM are persistent and associated with an increased risk for microvascular complications including retinopathy, especially with continued insulin omission [39–41]. Another study indicated that insulin omission was associated with poor regimen adherence and higher rates of neuropathy than individuals who did not omit insulin [42]. Studies of young women who omit insulin indicate they have disturbed eating attitudes and negative attitudes about diabetes, report previous symptoms of anorexia and bulimia, and report that they are not truthful with their physicians about self-management [43].

Several studies have examined eating disorders in patients with T2DM. Results indicate that patients with binge-eating disorder report greater difficulties with hunger, greater impairments to quality of life, disinhibited eating (often at night-time), have higher rates of anxiety disorder, have higher rates of body image disturbance, are more likely to be overweight, and also report elevated symptoms of depression [33,44,45]. In addition, binge eating in women with T2DM has been associated with poorer psychological well-being, increased BMI, decreased self-efficacy for adherence to diet and physical activity recommendations, and poorer glycemic control [46].

Treatments for eating disorders

Treating eating disorders in patients with diabetes is obviously complicated by the role of diet in diabetes management. Treatment options can range from outpatient treatment, partial hospitalization, and inpatient hospitalization depending on the severity of the eating disorder. However, there is a limited evidence base for the treatment of eating disorders in patients with diabetes. In the general population, psychological treatment such as CBT has empirical support for the treatment of binge-eating disorder and bulimia nervosa, with some support for CBT and family therapy in the treatment of anorexia nervosa [47]. Psychopharmacologic interventions including SSRI medications have also been useful in the treatment of eating disorders in the general population (mainly because of the association of eating disorders with depression and anxiety) [48].

For women with T1DM and eating disorders, a group administered CBT-based psychoeducational intervention was evaluated in a randomized controlled study, and was shown to reduce disordered eating but without change in glycemic

control or insulin misuse [49]. In a nonrandomized study, a small sample of women with T1DM and bulimia received an integrated multicomponent inpatient treatment (including CBT and family therapy) and were compared with a group of women receiving usual care: 3 years after the inpatient intervention, these patients had reduced symptoms of bulimia as well as improved psychological functioning and glycemic control [50]. Group therapy may be effective for treating eating disorders in patients with T2DM. One controlled study demonstrated reduced symptoms of binge eating at 3-month follow-up, and reductions in binge eating were associated with improved glycemic control [51].

Neurocognitive problems

Prevalence

A recent meta-analysis has shown that rates of cognitive impairment are higher among adults with diabetes than without diabetes [52]. In fact, research indicates that patients with T2DM have nearly double the risk of developing cognitive impairment and dementia [53]. Results of studies comparing cognitive dysfunction in T1DM versus T2DM patients have revealed differences in the kinds of cognitive impairments each group experiences: patients with T1DM tend to experience more changes in psychomotor speed and motor speed, while patients with T2DM may experience greater abnormalities in learning and memory [54].

Associated factors

There are several factors associated with cognitive impairment in patients with diabetes. Neurocognitive impairment is most often associated with chronic hyperglycemia [54,55], severe and frequent hypoglycemia [56], presence of microvascular complications including retinopathy and nephropathy [57], and comorbid health conditions such as hypertension and obesity, as well as longer duration of diabetes [54]. There is also evidence that cognitive impairment can make diabetes management especially challenging. In a study of older adults with T2DM, as cognitive impairment worsened, adherence to diabetes self-management tasks also declined, particularly for adherence to dietary and physical activity components of the regimen [58].

Treatment

Some evidence suggests that improving glycemic control may be helpful for cognitive impairments in older patients with diabetes [54,57,59]. Due to the association between poor glycemic control and cognitive decline, intensive insulin therapy to improve glycemic control should be used to improve cognitive functioning in patients with T1DM; in patients with T2DM, targeting risk factors such as hypertension and dyslipidemia may also be important to reduce cognitive dysfunction [54].

Future research needs

There is a large evidence base documenting the importance of psychological factors in diabetes management. However, more longitudinal studies with larger study samples should focus on the identification of specific psychosocial factors that influence regimen adherence and glycemic control over time in adults with T1DM and T2DM. For example, longitudinal studies can determine mechanisms to account for how psychosocial factors and health behaviors affect health over time. Results from such studies can inform the development of more effective interventions for specific patient populations. Sample sizes should be sufficient to detect effects among various patient subgroups who evidence specific psychological problems, including: ethnic minorities, low socioeconomic status, the elderly, those who live alone or without social and family support, those with diabetes-related health complications.

More research is needed to assess how to improve self-management skills, empowerment, coping skills and stress management to promote long-term health and quality of life for these special patient populations. Theory-based intervention studies are needed to determine how to individualize (i.e., tailor) psychosocial therapies to improve regimen adherence, glycemic control, and quality of life in the various patient populations.

Another research priority is to conduct multicenter clinical trials to document the efficacy of initial findings drawn from smaller, single-site intervention studies. Research should be conducted that evaluates the integration of psychosocial intervention into disease management program, for example by targeting high-risk patients. Cost-effectiveness trials in "real world" managed care settings are needed to assist in the translation of research findings to clinical practice. The effectiveness of behavioral and psychosocial interventions must demonstrated in clinical settings and shown to be cost-effective in order for more widespread implementation of these therapies to occur.

Recommendations for clinical practice

This review has demonstrated that psychological problems in adults with diabetes are common in clinical practice, and that these problems are associated with decreased self-management [60]. Studies show that physicians are aware of these difficulties and how they may compromise optimal management of diabetes, yet they are often uncomfortable and frustrated by how best to deal with them [61]. There has been a paradigm shift in diabetes care in recent years, with the recognition that optimal diabetes management requires an appreciation of the context of healthcare, the interplay of multiple environmental, psychological, social, and medical factors, and the adoption of a patient-centered, chronic rather than acute model of healthcare delivery [62]. The importance of the relationship between

physicians and other healthcare providers and their patients is critical [63], as is the provision of follow-up support over time [64].

The identification of psychological problems in clinical practice is a priority. Fortunately, there are a number of reliable and valid screening instruments that are brief, easy to score, and can be used in clinical practice. Depression in patients with diabetes is so common that has been referred to as "diapression" [65]. Clinicians can screen for depression using measures such as the Beck Depression Inventory-II [66], the seven-item Beck Depression Inventory-Primary Care scale [67], the Center for Epidemiological Studies-Depression scale [68], the Patient Health Questionnaire (PHQ-9) [69], or the Geriatric Depression Scale [70]. Many patients are also so stressed and anxious that their psychological distress impairs their ability to effectively manage their diabetes. The 20-item Problem Areas in Diabetes survey can be used to screen for diabetes-related psychosocial distress in patients with diabetes [71]. A more recent 17-item Diabetes Distress Scale can also be used to identify patients who feel overwhelmed with daily self-management [72]. Eating disorders in patients with diabetes—especially women—are prevalent, persistent, and lead to increased risks for health complications [73]. The Eating Disorder Examination-Questionnaire can be used to screen for the presence of eating disorders [74]. Other easy-to-use measures for screening are the Eating Attitudes Test [75] and the Eating Disorders Diagnostic Scale [76].

It is obviously critical to have skilled mental health professionals—knowledgeable about diabetes and its treatment—as part of the interdisciplinary healthcare team. In many clinical settings, however, there are financial barriers to having psychologists, social workers, and psychiatrists as part of the clinic team, so that making referrals is the most common clinical practice. Unfortunately, many patients do not follow-through with mental health referrals. Nevertheless, it is important for physicians to conduct screening for psychological problems using reliable and valid questionnaires such as those described earlier as a first step; patients who screen positive can then be counseled and referred directly to the mental health professional associated with the diabetes team. Given the complexity of assessment for neurocognitive difficulties, referral to a clinical psychologist or neuropsychologist must be made to adequately determine patients' neurocognitive functioning, a more time-consuming and often costly evaluation.

Optimal diabetes self-management can be improved by addressing psychological problems in clinical practice, especially when clinicians work collaboratively with patients. Research has demonstrated that interventions to increase patient empowerment lead to improved patient outcomes in terms of psychological functioning, diabetes self-management behaviors, and glycemic control [77]. There is some evidence for the efficacy of cognitive-behavioral therapies in managing depression [13], anxiety [20,24,25], and eating disorders [49,51] in patients with diabetes. Interventions addressing intrinsic motivation, healthy coping, and problem-solving skills have also led to improved patient outcomes [78–80].

Conclusions

Psychological problems in patients with diabetes such as depression, anxiety, eating disorders, and neurocognitive difficulties, are common and associated with increased risk for poor patient outcomes including compromised quality of life, reduced self-management behaviors, poor glycemic control, and microvascular and macrovascular complications. It is critical to address these problems in clinical practice. Reliable and valid questionnaires with good clinical utility are available to screen for depression, anxiety and distress, and eating disorders. Psychological interventions utilizing cognitive-behavior therapy have improved patient outcomes. Inclusion of mental and behavioral health professionals as part of interdisciplinary treatment teams and adoption of the chronic care model of care recognizing patient autonomy is recommended in order to effectively manage psychological problems in clinical practice.

Glycated hemoglobin, serum proteins, and other markers as tools for monitoring

Susan M. Gerber[1], Douglas F. Stickle[2], Intekhab Ahmed[2] and Serge A. Jabbour[2]

[1]Cooper Medical School of Rowan University, Cooper University Health Care, Camden, NJ, USA

[2]Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA, USA

Key points

- Technological advances have greatly improved our ability to monitor glycemic control in patients with diabetes. One of the most important clinical advances in modern diabetes care is the ability to estimate an integrated value of glucose excursions over several months, providing a useful window for glucose monitoring called the hemoglobin A1c (HbA1c) test.

- A physician using one of several available glycated hemoglobin assays for patient management needs to be familiar with what form of the modified protein has actually been measured. These considerations will affect the clinical implications of the test results.

- The Diabetes Control and Complications Trial (DCCT) demonstrated the relationship between elevated HbA1c and risk of development of diabetic complications, and provided the impetus for the standardization of HbA1c assays.

- Many studies, including the DCCT, support long-term control of diabetes with monitoring of glycemia using the HbA1c.

- Currently, sufficient standardization of the various HbA1c assays has been achieved such that the results can be applied to populations in a uniform and time-specific fashion. Thus HbA1c is recommended as a screening test for diabetes and for risk stratification by detecting asymptomatic persons with prediabetes and allowing for appropriate lifestyle interventions.

- HbA1c testing offers the advantages of a non-fasting test, increased stability prior to analysis, and fewer fluctuations from patient stressors or illness.

- The A1c-Derived Average Glucose Study demonstrated a linear relationship between HbA1c and estimated average glucose (eAG) eAG, showing that HbA1c is an accurate measurement of average blood glucose over time and supporting the interpretation of HbA1c in the more familiar units used for blood glucose—the same units that patients use for self-monitoring of their blood glucose (SMBG).

- Fructosamine assays may be used in clinical settings to detect short- to medium-term changes in mean blood glucose. Fructosamine assays also assist in certain clinical conditions where measurement of HbA1c is considered less reliable.

- 1,5-Anhydroglucitol testing is a marker of glycemia that responds more readily to glucose trends than HbA1c, and also offers the advantages of a simple blood test that is metabolically stable and shows small biological variability.

- Protein glycation products undergo rearrangements towards the development of advanced glycosylation end-products, which have been associated with chronic complications of diabetes, including tissue damage and cardiovascular disease.

- The continuous glucose monitoring (CGM) device has made possible the concept of the "artificial pancreas" when linked with insulin pump technology for continuous subcutaneous insulin infusion controlled by a computer-run insulin delivery algorithm. Use of this closed-loop system to eliminate SMBG, monitoring with surrogate markers such as HbA1c, and self-adjustment of insulin may enable diabetic patients to reach previously elusive near-normal HbA1c levels with fewer extremes of hypo- and hyperglycemia and diabetic complications.

Introduction

Technological advances have greatly improved our ability to monitor glycemic control in patients with diabetes. The wide availability of relatively inexpensive handheld meters, for example, has facilitated the monitoring of spontaneous blood glucose levels at various times during the day. However, the notorious fluctuation of postprandial glucose values is a common source of frustration in patients with diabetes, as well as the physicians and nurses trying to determine the level of their glycemic control over a longer time frame. To this end, one of the most important clinical advances that has improved modern diabetes care is the recognition that glucose undergoes nonenzymatic chemical reactions with various proteins in

the blood, including hemoglobin, in a manner that allows the estimation of an integrated value of the glucose excursions over a period of weeks to months, providing a useful window for glucose monitoring using the hemoglobin A1c (HbA1c) [1,2]. The early 1980s also saw the emergence of a second group of tests, collectively called "fructosamine," that were based on a determination of glycated serum proteins, especially albumin, and found to be useful for similar clinical purposes over a shorter time period than that for the HbA1c [3,4]. There has also been growing interest in utilizing measurement of advanced glycosylation end-products (AGEs) in serum and in tissues as laboratory correlates of some of the chronic tissue damage observed in patients with diabetes [5]. In the present chapter, starting from a chemical description of the glycation reactions, we will present the pathophysiologic background necessary for an understanding of the variety of tests now used for glycated hemoglobin (GHb) and albumin determination and their interpretation in different clinical encounters. We will discuss the use of anhydroglucitol as a monitor of glucose. We will provide an overview of the standardization of HbA1c measurement and reporting, as well as the use of HbA1c for diabetes screening and risk category stratification. We will briefly describe AGEs and their potential relationship to the chronic complications of diabetes. Finally, we will examine future directions of diabetes care.

Glycation reactions

During the early part of the twentieth century, Amadori, Maillard, and others characterized the fundamental chemical reactions that underlie the formation of HbA1c and more advanced protein products associated with aging and tissue damage [6,7]. Chemically, the basic reaction involves covalent attachment of the aldehyde group of an acyclic glucose molecule to protein amino groups (Figure 59.1). The first step of this reaction, resulting in the formation of a Schiff base, can be transient and reversible, while the second step yields a fixed ketoamine product. The potential clinical utility of these observations stems from the appreciation that these slow, nonenzymatic processes occur *in vivo*, and that the accumulation of protein glycation products is significantly increased in patients with hyperglycemia [8,9]. The best known of these products is GHb and its related derivatives, including the HbA1c subfraction, which has evolved over the past several decades from an intriguing finding in diabetic patients [10] to become a critically important clinical variable to evaluate the level of glycemic control in patients with diabetes over time [11–13]. In addition, protein glycation products undergo further rearrangements towards the development of AGEs, which have been associated with chronic complications of diabetes, including tissue damage and cardiovascular disease, as discussed later [4,5].

In solution, the native glucose molecule exists primarily as an inert closed-ring structure. The open form, constituting 0.001%

of the dissolved glucose, however, has a reactive aldehyde group with a unique capacity to bind covalently with proteins, generally to the free ε-amino group of lysine side chains [14]. In hemoglobin A (HbA), the amino group of the β-chain N-terminal valine is also highly reactive with glucose [15,16]. In both instances, the initial product is the unstable Schiff base or aldimine linkage, which may dissociate or spontaneously progress to a ketoamine or Amadori product, which is only partially reversible [17] (Figure 59.1). The rate of formation of the Schiff base depends predominantly on the ambient glucose concentration, while the formation of ketoamine is influenced by both the glucose concentration and the time of exposure of the protein to glucose [18–20].

Glycation of hemoglobin

The glycation of HbA, leading to the formation of HbA1c and other derivatives, is the best characterized of the clinically important protein glycation reactions, and is unique in several respects. One is the novel formation of a linkage between glucose and the amino group of the N-terminal valine of the hemoglobin β chain, which serves as a unique recognition target for clinical biochemical assay methods, as described later [21]. Secondly, in contrast to the glycation of other serum proteins, it is crucial to recognize that the glycation of HbA is an *intracellular* process. Thus, determinants of the concentration of glucose within the red cells as well as factors that affect the turnover and lifespan of the erythrocytes will strongly influence the level of GHb.

Glucose first enters red blood cells by facilitated diffusion through membrane transport proteins with a Michaelis constant of about $0.5–2.0 \, \text{mmol L}^{-1}$ [22]. The intracellular glucose is phosphorylated by hexokinase and enters the three major pathways of erythrocyte glucose metabolism, including glycolysis to pyruvate/lactate, formation of 2,3-bisphosphoglycerate, and the pentose phosphate pathway. The activity of hexokinase and all three major metabolic pathways declines exponentially during the life of the red cell, with a major loss of enzyme activities during the transition from reticulocyte to mature cell [23]. The loss of intracellular capacity to metabolize glucose causes a more rapid equilibration of extracellular glucose within the intracellular compartment and can lead to a subsequent rise in the glycation of hemoglobin in aging red cells. Further support for this hypothesis comes from the finding that HbA1c concentrations are increased in nondiabetic patients with altered erythrocyte glucose metabolism such as those with glucose-6-phosphate dehydrogenase deficiency [24]. Interestingly, GHb is virtually undetectable in porcine red cells, since glucose transport across the pig erythrocyte membrane is very limited, and this minimizes the intracellular content of free glucose [25].

As pointed out earlier, glycation may also occur at other sites on hemoglobin, which may be detected or missed by some
Figure 59.1 Reaction of glucose with the NH2-terminal amino group of the β-chain of hemoglobin A (βA-NH2) to form an aldimine linkage or Schiff base structure. This is an unstable structure (also called pre-A1c) that can undergo rapid reversal to the two initial components. Alternatively, a slower reaction occurs involving an Amadori rearrangement to the more stable ketoamine linkage, forming HbA1c.

of the routinely used methods for measuring GHb [14,15]. Thus, ion-exchange chromatography, operating on the basis of a charge difference, separates hemoglobin modified at the N-terminal valine, while weak acid hydrolysis detects all the glycation sites of HbA that occur with varying degrees of reactivity (see later). Therefore, a physician using one of several available GHb assays for clinical patient management needs to be familiar with what form of the modified protein has actually been measured. These considerations will affect the clinical implications of the test results [2,26].

Nomenclature

Glycosylation should be reserved to describe the enzymatic transfer of carbohydrates to proteins, such as during protein biosynthesis and posttranslational processing. In contrast, *glycation* is the term that best describes the process of nonenzymatic bonding of glucose to proteins, as in the formation of HbA1c. The most commonly employed tests for GHb in current clinical practice involve the following glycated protein derivatives:

1 *Hemoglobin A (HbA)* is "native" hemoglobin consisting of the unmodified globin tetramer formed from two α- and two β chains.

2 *Total glycated hemoglobin (GHb)* includes glycation at the N-terminal valine of β-globin in HbA (the actual HbA1c component) as well as additional derivatives including glycation at other valines and lysines in the hemoglobin molecule. GHb also encompasses glycation of other hemoglobin types (HbS, HbC, HbF, and so on).

3 *Hemoglobin A1 (HbA1)* refers to all the glycated species derived from adducts to the N-terminal valine in the β chain of HbA. It consists of several components classified according to the nature of the carbohydrate moiety. For example, fructose-1,6-diphosphate forms HbA1a1, glucose-6-phosphate forms HbA1a2, and so on.

4 *Hemoglobin A1c (HbA1c)* is a component of HbA1 formed by nonenzymatic addition of glucose to the N-terminal valine of the β-chain of HbA. As it is a subfraction of GHb and HbA1, HbA1c content is always a smaller percentage compared to the other two.

5 *Hemoglobin A0 (HbA0)* is a major component of HbA that is posttranslationally modified, including addition of sugars but without an N-terminal valine adduct to the β chain.

Glycation in individuals with normal glucose tolerance

Kinetics of glycation

Studies in normoglycemic individuals with radiolabeled iron documented that HbA1c increases linearly during the lifespan of the erythrocyte [18], with the lowest HbA1c content in the youngest population of erythrocytes and the highest content in the oldest cells [27]. In patients with diabetes, this relation is less clear, reflecting day-to-day changes in the serum glycemic profiles [27]. At any rate, there is no evidence that there is a certain period of the erythrocyte lifespan when glycation occurs selectively. From these considerations it also follows that conditions causing a reduced lifespan of the erythrocytes will cause a reduction in measured HbA1c concentration [21]. In fact, it has been proposed that measurement of HbA1c may serve as a measure of the erythrocyte lifespan in individuals with normal glucose tolerance and without a hemoglobinopathy [28].

Glycated hemoglobin in nondiabetic populations

The range of HbA1c values varies significantly in the normal population. Several groups of investigators have attempted to determine the factors associated with the distribution of HbA1c in nondiabetic individuals. From these studies it is clear that variation in the erythrocyte lifespan does not seem to be the sole cause of variation in normal HbA1c values [29,30]. In the large, cross-sectional "France Telecom" study, involving 3240 subjects without known diabetes, pregnancy, or hemoglobinopathies, HbA1c rose with deterioration in glucose tolerance, age, body mass index (BMI), family history of diabetes, as well as in women with a history of delivering large babies, and after menopause [29]. No difference in the HbA1c was noted between males and females, and in both sexes HbA1c was higher in smokers than in nonsmokers. Although some

seasonal variation was observed, it did not assume a consistent pattern over a 2-year period of observation. In a stepwise multiple regression analysis, the most significant factors associated with HbA1c level were age followed by fasting plasma glucose (FPG) [29]. Even so, the strongest correlation (i.e., between HbA1c and FPG) was strikingly low ($r = 0.20$). Yudkin et al. [30] identified among nondiabetic individuals those who had relatively elevated or depressed GHb values, as confirmed by four different methods. The low and high glycators represented approximately 20% of the study population. The observed variation in GHb could not be explained on the basis of glucose level, age, gender, BMI, hemoglobin levels, smoking, dietary habits, or vitamin intake.

Standardization of the HbA1c assay

Because some of the variation in HbA1c levels in normal populations may be poorly explained by glycemia, and because HbA1c testing was previously poorly standardized over the years, it had been difficult to recommend the use of these tests as a method of screening for diabetes mellitus or for monitoring treatment of diabetes in practice [31,32]. However, the Diabetes Control and Complications Trial (DCCT) published in 1993 demonstrated the relationship between elevated HbA1c and risk of development of diabetic complications, and provided the impetus for the standardization of HbA1c assays [33]. In the 1990s, the United States (US), Japan, and Sweden were utilizing a variety of HbA1c analyses with varying results from different laboratories [34]. The American Association for Clinical Chemistry formed a workgroup in 1993 to help standardize the HbA1c assays to make the results directly traceable to the DCCT. This workgroup produced an HbA1c standardization protocol and subsequently dissolved. In its place, in 1996, the US formed the National Glycohemoglobin Standardization Program (NGSP). The NGSP reference method uses ion-exchange high-performance liquid chromatography (HPLC), and laboratories and manufacturers of testing equipment can be certified through the NGSP if their instruments are calibrated to match results from the NGSP method [35]. Sweden and Japan also began their own analogous HbA1c standardization programs in the 1990s using direct comparison methods [34]. The methods used in these countries were not traceable to the NGSP, creating a lack of international standardization. Further, the NGSP reference method also measured other constituents in addition to HbA1c, making its methodology not metrologically sound [35].

As a result, in 1995, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) formed a Working Group on Standardization of HbA1c to address the differences in HbA1c results reported by these countries' standardization programs. The goal was to find a specific assay solely for HbA1c that would be accepted as an international standard with metrological traceability. The IFCC did successfully develop a specific HbA1c assay using mass spectrometry and capillary electrophoresis that has been approved by all its member societies and is utilized in a worldwide network of reference laboratories [35]. This has provided a global anchor for metrological traceability using the IFCC reference measurement system and has thus improved intra-assay and inter-assay coefficients of variation in HbA1c results [36]. However, because of the complicated process and expensive equipment needed, clinical laboratories can only afford to use the IFCC reference method to calibrate their instruments before processing routine samples using other HbA1c assays. Additionally, because the IFCC HbA1c assay is specific, the normal range for HbA1c using the IFCC reference method is approximately 2% less than previous normal ranges and must be expressed in mmol A1c/mol hemoglobin in order to be metrologically correct [35]. The IFCC recommended that a percentage not be used to convey HbA1c results as this was not metrologically sound. Given this recommendation and the potential for ensuing confusion, another workgroup was convened to give recommendations for HbA1c reporting. In 2007, the IFCC, the American Diabetes Association (ADA), the International Diabetes Federation (IDF), and the European Association for the Study of Diabetes (EASD) put forth a consensus statement recommending reporting of HbA1c in IFCC units, NGSP units, and adding a third requirement for reporting called estimated average glucose (eAG, either in $mg\,dL^{-1}$ or $mmol\,L^{-1}$) if the designated targets of the A1c-Derived Average Glucose (ADAG) Study were reached [37]. This study was designed to demonstrate a direct relationship between HbA1c and average blood glucose such that the HbA1c results could be reported in $mg\,dL^{-1}$ or $mmol\,L^{-1}$ in deference to the initial IFCC recommendation against reporting HbA1c as a percentage. Previous studies, such as the DCCT, contained limited amounts of blood glucose data performed over a short period of time in a small number of participants, and were not intended to show the relationship between HbA1c and average blood glucose [35].

Estimated average glucose (eAG) reporting

The ADAG trial results were published after the consensus statement was released. An international multicenter trial sponsored by the ADA, EASD, and IDF, the ADAG trial determined the mathematical relationship and reliability of the correlation between HbA1c and eAG. The study included type 1 and type 2 diabetics and people without diabetes. Participants used continuous glucose monitors as well as traditional self-monitored blood glucose (SMBG), generating approximately 2700 glucose measurements per participant. The ADAG trial demonstrated a linear relationship between HbA1c and eAG and generated the following equation—derived from population regression of mean blood glucose (MBG) on HbA1c—to describe this correlation: $[28.7*HbA1c_{(\%)}]\text{-}46.7 = AG_{(mg\,dL^{-1})}$. This trial showed that HbA1c is an accurate measurement of average blood glucose over time, and supported the interpretation of HbA1c in the more familiar units used for blood glucose—the same units that patients use for SMBG [38].

A second consensus meeting on standardization of HbA1c was convened at the IDF meeting in 2009, and that consensus statement, published in 2010, affirmed that the IFCC reference system is the only valid anchor for HbA1c standardization, and that HbA1c results should be dually reported in mmol/mol and derived NGSP units (%) using the IFCC-NGSP master equation $NGSP_{(\%)} = [0.09148 * IFCC_{(mmol\,mol^{-1})}] + 2.152$. eAG was mentioned for possible use in discussion with patients but was not required for reporting [39]. The results of a third consensus meeting in December 2011 have not yet been published [40]. Concern about adopting IFCC units, especially with regard to physician and patient education, has made US agencies and laboratories hesitant to implement its use. For the immediate future, the US has no plans to require IFCC units for HbA1c reporting. IFCC unit adoption remains controversial and each country has individually decided whether to proceed with its usage [41].

Mean blood glucose versus estimated average glucose

Mean blood glucose (the average blood glucose expressed on a patient's personal glucometer) may differ from eAG. One study found the eAG either over- or underestimated MBG by approximately $28\,mg\,dL^{-1}$ in one third of patients, translating to an HbA1c difference of approximately 1% [42]. In patients with a higher HbA1c, the 95% confidence interval (CI) for the attendant eAG is wider, reflecting greater uncertainty. Also, because patients are more likely to check SMBG preprandially and at other times when blood glucose is often lower, the MBG is often lower than the eAG, which includes episodes of postprandial hyperglycemia. Patients should be made aware that these estimates are part of the range of the "true mean" of their blood glucose measurements [35].

HbA1c as a screening test for diabetes

Currently, sufficient standardization of the various HbA1c assays has been achieved such that the results can be applied to populations in a uniform and time-specific fashion. This finding led the International Expert Committee and the ADA in 2009 to recommend the use of HbA1c as a screening test for diabetes. The threshold HbA1c for diagnosis is 6.5% or higher, the cutpoint above which an increased prevalence of retinopathy is found. It is recommended that an HbA1c assay standardized or traceable to the DCCT reference assay and certified by the NGSP be used. Virtually all central laboratory methods in use in the US are certified to conform to the NGSP standard. It is not recommended to use point-of-care HbA1c assays for diagnostic purposes given their insufficient accuracy [43].

HbA1c testing offers the advantages of a non-fasting test, increased stability prior to analysis, and fewer fluctuations from patient stressors or illness. However, HbA1c testing is more expensive than fasting plasma glucose (FPG) and oral glucose tolerance testing (OGTT), and is not available everywhere in the world. Despite the lower sensitivity of HbA1c testing than FBG

or OGTT, HbA1c testing may detect more cases of diabetes due to increased convenience. Additionally, there may be incomplete correlation between eAG and HbA1c in some individuals, and the possibility of increased glycation in some races/ethnic groups remains controversial. Finally, the epidemiologic studies on HbA1c from which recommendations of HbA1c cutpoints for diabetes diagnosis have been issued have all been performed in adults. Consequently, the optimal HbA1c cutpoints for diagnosis of T2DM in children remain uncertain [43].

In conditions that involve abnormal red blood cell turnover (such as some anemias, and recent transfusions or blood loss), HbA1c cannot be used for diabetes diagnosis. In the presence of hemoglobin variants, an HbA1c assay with which the abnormal hemoglobins do not interfere should be used for A1c analysis. Generally this means that A1c should be measured by a glycated hemoglobin assay which is in turn calibrated to A1c [43].

Screening for diabetes should begin no later than age 45 given that age is a major risk factor for the development of diabetes. Asymptomatic adults who are overweight and have at least one other risk factor such as hypertriglyceridemia, high-risk ethnicity (i.e., Pacific Islander) or race, sedentary lifestyle, hypertension, low HDL-cholesterol, PCOS, acanthosis nigricans, cardiovascular disease, previous impaired glucose tolerance (IGT) or impaired fasting glucose (IFG) or HbA1c $\geq$5.7%, history of delivering a baby heavier than 9 lbs, or history of gestational diabetes mellitus (GDM) should be screened for diabetes mellitus regardless of age. If the results are normal, testing should be repeated every 3 years. If testing is abnormal, screening should be repeated more frequently [43].

HbA1c used for risk stratification

The Expert Committee on Diagnosis and Classification of Diabetes Mellitus in 1993 and 2007 has recognized a category of increased risk for diabetes called prediabetes. Prediabetes is defined as an elevated blood glucose that—while abnormal—does not meet criteria for diabetes, but marks an individual who is at high risk for developing diabetes and cardiovascular disease in the future. The risk rises in a curvilinear fashion with increase in HbA1c. Prediabetes can be quantified via FBG or OGTT as well as HbA1c. In terms of HbA1c, prediabetes exists when HbA1c is between 5.7 and 6.4% [43]. A systematic review of 16 cohort studies involving approximately 44,000 persons over an average follow-up interval of 5.6 years showed that those with a HbA1c of 5.5–6.0% had a moderately increased relative risk of diabetes (9–25% 5-year incidence), and those with a HbA1c of 6.0–6.5% had a 5-year risk of developing diabetes between 25–50%, with a 20 times greater relative risk than persons with an HbA1c of 5.0% [44].

Diabetes is often diagnosed after complications appear. Appropriate screening at the above intervals can reduce potential glycemic burden and risk of attendant diabetes complications by detecting asymptomatic persons with prediabetes and allowing for appropriate lifestyle interventions.

HbA1c as a unique index of glycemic control in type 1 diabetes

In diabetic patients, the HbA1c can provide the physician with a valuable monitor of the adequacy of control of hyperglycemia. Interestingly, early studies showed that physician judgment about the quality of the antecedent glycemic control based on historical and laboratory data (glycosuria and fasting and random glucose tests) was frequently discordant with the actual data provided by measuring the GHb [45]. Knowing the HbA1c has gradually become a fundamental feature of modern diabetes care. As a time-averaged monitor of blood glucose, it prompts the physician to work with the patient to intensify management when necessary in order to achieve treatment goals [46]. Measurement of HbA1c is especially valuable in T1DM when day-by-day oscillations in glycemia tend to be highly variable, making an accurate assessment of the adequacy of diabetic treatment based on home blood glucose measurement very difficult. In this respect, if there is frequently a discrepancy between glucose values and the HbA1c, with few rare exceptions (discussed in more detail later), the latter is usually more correct [47].

The overall utility of the HbA1c in adjusting diabetes therapy is tempered by the fact that while it can help to identify patients with poorly controlled hyperglycemia, a high level by itself cannot guide the physician toward specific adjustments in the insulin regimen [48]. The HbA1c is thus an important ancillary test to be used in the ongoing assessment and treatment planning for the diabetic patient. Comparison of the HbA1c with the patient's own capillary glucose testing enables the physician to alter therapy, especially the timing and amount of multiple insulin injections, to improve the overall diurnal glycemic control.

HbA1c testing for diabetes screening and monitoring in pregnancy

Previously, gestational diabetes mellitus was defined as any hyperglycemia or glucose intolerance diagnosed during pregnancy, whether or not the condition persisted postpartum or may have preceded the onset of pregnancy. Given the increased prevalence of T2DM in women of childbearing age, the current guidelines recommend screening those women with risk factors for T2DM at the first prenatal visit using standard diagnostic criteria. Women who meet diagnostic criteria at the first prenatal visit are diagnosed with overt diabetes, not gestational diabetes (GDM) [43].

Maternal hyperglycemia in early pregnancy can lead to an increased incidence of fetal malformations and wastage, and poor glycemic control during later pregnancy is associated with perinatal morbidity [49]. After the results of the international multicenter epidemiologic Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study [50] of ~25,000 pregnant women were published in 2008 demonstrating that

risks of poor maternal, fetal and neonatal outcomes increased continuously with increasing maternal blood glucose at 24–28 weeks—even at glycemic ranges previously deemed normal during pregnancy—the diagnostic criteria for GDM were revised by the International Association of Diabetes and Pregnancy Study Groups (IADPSG), a consensus group convened in 2008–2009. All women who are not known to have overt diabetes are now screened between 24–28 weeks gestation for GDM using a 75-g OGTT. Additionally, new diagnostic criteria for the OGTT results were set based on odds ratios for adverse outcomes compared with the mean glucose levels of HAPO study participants [43]. The diagnosis of GDM is now made if any one of the following is found during OGTT: a FBG (after 8-hour fast) of $\geq 92\,\mathrm{mg\,dL^{-1}}$ ($5.1\,\mathrm{mmol\,L^{-1}}$), 1-hour BG of $\geq 180\,\mathrm{mg\,dL^{-1}}$ ($10.0\,\mathrm{mmol\,L^{-1}}$), and/or a 2-hour BG of $\geq 153\,\mathrm{mg\,dL^{-1}}$ ($8.5\,\mathrm{mmol\,L^{-1}}$). This is also a change in that only one abnormal value is now needed to make the diagnosis, which will increase prevalence of diagnoses of GDM. In 2011, the American College of Obstetrics and Gynecology recommended reverting to use of the previous World Health Organization (WHO) diagnostic criteria for GDM [43]. A systematic review of the WHO and the IADPSG criteria for GDM diagnosis published in 2012 showed that both criteria identified women at a small increased risk for adverse pregnancy outcomes, with associations of similar magnitude for each criteria, but with a high level of inconsistency for the newer IADPSG criteria [51]. Further studies are needed to better characterize the IADPSG criteria.

It is recommended that women with GDM undergo screening for underlying previously undiagnosed overt T2DM at 6–12 weeks postpartum, using nonpregnant OGTT diagnostic criteria. It is not recommended to use HbA1c for diagnosis of overt diabetes at that time because of the antecedent treatment for hyperglycemia [52]. Given their increased risk of development of overt diabetes [53], women with a history of GDM must be followed with periodic screening for prediabetes or diabetes [43]. There remains considerable confusion regarding the wide array of assays available to clinicians in the US, including testing conforming to both the ACOG and IADPSG diagnostic criteria. This reflects the ongoing debate between proponents of the HAPO study who reiterate the potential benefits of having a universal test to diagnose GDM, a common disease whose treatment offers great potential benefit to mothers and babies, and those who critique the HAPO study results as being merely observational and use of its diagnostic criteria as the cause of inappropriate over-diagnosis of GDM [54,55].

In pregnant patients with preexisting diabetes, the recognition that the risk of fetal malformations rises sharply with poor diabetic control prompted the use of HbA1c assays at the first prenatal visit to evaluate the patient's glycemic control over the initial few weeks of gestation [56]. Conversely, the results of multiple nonrandomized trials showed significantly lower rates of congenital malformations in babies born to diabetic women who participated in preconception care programs with

multidisciplinary support to train patients how to intensively manage their diabetes through diet, insulin use, and SMBG, with a goal of normalization of HbA1c prior to conception [57].

Ideally, the diabetic patient's blood glucose levels should be managed aggressively prior to conception to achieve a normal or near-normal HbA1c value and minimize the risk to the fetus early in gestation. However, almost two-thirds of pregnancies in diabetic women are not planned [43], and the early HbA1c value may be used in counseling the patient with regard to possible effects on the fetus [57,58]. Multiple medications used to treat diabetes and associated complications (such as statins) are contraindicated during pregnancy, and appropriate pregnancy prevention counseling must be provided to women of childbearing age prior to beginning these therapies. NPH, regular, lispro, aspart, and detemir insulins are pregnancy category B (no evidence of risk in humans). Glargine and glulisine insulins are category C, with insufficient data to establish safety in pregnancy. Metformin and acarbose are pregnancy category B, and all other oral antihyperglycemics are category C [43].

Frequent measurement of HbA1c is a useful adjunct to self-monitoring of blood glucose during a diabetic pregnancy. Since tight regulation of glycemic excursions is an important goal, HbA1c measured at 6-week intervals can help in the overall assessment of the mean blood glucose as estimated from fasting and postprandial capillary values [59]. As in nonpregnant patients with diabetes, the HbA1c value should corroborate the glucose testing results and lead to a reassessment of the diabetic regimen if poor control is suggested [60]. It is important to note here that the average blood glucose concentration is about 20% lower in normal pregnant women than in nonpregnant women, leading to a small reduction in HbA1c values; so the reference range for HbA1c during pregnancy should be 20% lower than in normal people [59,60].

HbA1c and chronic complications of diabetes

In long-lived proteins, once glycation has occurred, the protein modifications progress to more complex derivatives called AGEs. The involvement of AGEs in diabetic complications has been suggested by the observation that there is no significant correlation between the presence or severity of chronic complications of diabetes and the HbA1c level if the duration of observation is less than 2 years [61–64]. Conversely, observations exceeding the threshold of 2 years have revealed an association of elevated HbA1c with the development or progression of diabetic retinopathy, nephropathy, and neuropathy.

Early studies demonstrated that HbA1c was clearly predictive of the chronic complications of diabetes. In the seminal work by Klein and colleagues [65] on more than 1800 patients with diabetes, HbA1c at the initial examination was predictive of the 4-year incidence and progression of diabetic retinopathy. In the group with onset of diabetes at less than 30 years of age,

who were all treated with insulin, those with HbA1c above the highest quintile compared with those below the lowest quintile had 1.9 times increased risk for developing any form of retinopathy; the relative risks for proliferative retinopathy and for the progression of retinopathy were 21.8 and 4.0, respectively. In older onset patients not treated with insulin, the same comparison yielded a relative risk for any form of retinopathy of 4.0 and a relative risk for progression of 6.2. Further early studies confirmed that over a period of 3–9 years, microalbuminuria was 3.6 times and retinopathy 2.5 times more prevalent in patients with mean HbA1c over 12.3% than in those with mean HbA1c less than 10.9% [66]. This group also showed that none of the patients developed retinopathy and microalbuminuria if their GHb was consistently below 9.0% (using a normal range of 6.3–8.2%).

The strongest data supporting that long-term control of diabetes with monitoring of glycemia using the HbA1c provides an index of the risk for development of microvascular diabetic complications comes from the DCCT [33]. This multicenter, 9-year study in a cohort of 1441 patients with T1DM compared conventional insulin therapy with diabetes management intensified by multiple daily insulin injections or use of an insulin infusion pump and rigorous attention to glycemic control. The intensive treatment resulted in significantly better glycemic control as estimated by HbA1c measurements, reduced from ~9% in the conventionally treated group to ~7% in the intensively treated group. In the primary prevention group (no signs of retinopathy at the start of the study) intensive insulin therapy reduced the onset of retinopathy by ~34%, and reduced microalbuminuria and clinical neuropathy by 35 and 60%, respectively. In addition, there appeared to be a continuous relationship between the HbA1c level and the risk of sustained progression of retinopathy in the entire study cohort. Consistent with these data is the notion that the higher incidence of chronic diabetic complications in the patients with elevated HbA1c was somehow causally related, perhaps through a similar mechanism involving protein glycation in target tissues.

A follow-up study to the DCCT, called the Epidemiology of Diabetes Intervention and Complications (EDIC), looked at the effects of intensive control on retinopathy, nephropathy, and neuropathy. It also examined incidence of cardiovascular (CV) events and the impact of intensive control on CV risk, and found that intensive blood glucose control reduced risk of any CV event by 42%, and reduced risk of nonfatal myocardial infarction, cerebrovascular accident, or death from CV cause by 57% [67].

In a large cohort of more than 5000 patients with T2DM, the United Kingdom Prospective Diabetes Study (UKPDS) similarly reported that intensive treatment of glycemia using lifestyle modification in addition to oral agents and insulin, resulting in a lowering of the group mean HbA1c from 7.9 to 7.1%, was associated with a marked reduction in microvascular complications of diabetes [68]. In the updated epidemiologic analysis of the UKPDS data, each 1% reduction in updated
Figure 59.2 Incidence rates and 95% confidence intervals for myocardial infarction and microvascular complications by category of updated HbA1c concentration, adjusted for age, sex, and ethnic group, expressed for White men aged 50–54 years at diagnosis and with mean duration of diabetes of 10 years. Source: Stratton 2000 [69]. Reproduced with permission of BMJ Publishing Group Ltd.

mean HbA1c was associated with reductions in risk of 21% for any endpoint related to diabetes, 21% for deaths related to diabetes, 14% for myocardial infarction, and 37% for microvascular complications, with no threshold of risk observed for any endpoint [69]. Although not strictly proven in the intervention trial, these observational data suggest that in patients with T2DM, any reduction in HbA1c is associated with reduced risk of complications including CV events, even with values extending into the normal range (<6%) (Figure 59.2).

In the Norfolk cohort of the European Prospective Investigation of Cancer and Nutrition (EPIC-Norfolk), HbA1c was a predictor of death from cardiovascular and all causes in 4662 men aged 45–79 not known to be diabetic [70]. HbA1c was continuously related to subsequent all-cause, cardiovascular, and ischemic heart disease mortality through the whole population distribution, with lowest rates in those with HbA1c concentration below 5%. An increase of 1% in HbA1c was associated with a 28% increase in risk of death independent of age, blood pressure, serum cholesterol, BMI, and cigarette-smoking habit. These provocative data suggest that the level of HbA1c even within the normal range may be closely associated with excess mortality in a population of men not known to be diabetic.

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial was a multicenter randomized trial comparing current diabetes practice guidelines with intensive blood glucose control, lipid reduction, and blood pressure control

in 10,000 patients with established T2DM for an average of 10 years. All study participants also had high risk of future CV events due to either preexisting CV disease, evidence of subclinical CV disease, or two or more CV disease risk factors. All participants took part in the blood sugar control portion of the trial, and were additionally enrolled either in the blood pressure trial or the lipid trial. The results showed that decreasing blood pressure to below currently recommended levels did not decrease risk of fatal or nonfatal CV events. Also, treatment of study participants with statin plus fibrate did not decrease risk of CV events over statin alone. Goal HbA1c in the intensive blood glucose control group was <6.4%, achieved in half of the intensive control group. The National Heart, Lung, and Blood Institute discontinued the intensive blood glucose portion of the study in 2008 due to safety concerns, as there was a 22% increased rate of death in the intensive blood glucose control group, which was statistically significant. A trend was seen toward a lower rate of CV events, mostly nonfatal myocardial infarction, in the intensive BG control group. However, it was felt that the possible harm outweighed the potential benefit in this group. No specific cause for the higher death rate among the intensive blood sugar treatment group could be identified [71].

Assays of glycated hemoglobin

Different analytical procedures measure one or more of the glycated species of HbA denoted as HbA1, HbA1c, or GHb (Table 59.1). Generally, the currently available technology can be divided into two major groups. The first group consists of techniques where separation of glycated and nonglycated hemoglobin is based on the charge difference between HbA1 and HbA0, including ion-exchange chromatography, high performance liquid chromatography (HPLC), isoelectric focusing, and agar gel electrophoresis. The second group is based on the presence of glucose within the glycated species; thus, by definition, these techniques measure total GHb. A third group uses immunoassay techniques using new monoclonal

antibodies with idiotypes that specifically recognize the glucose adduct of the N-terminal valine of HbA in the HbA1c molecule.

As noted previously, the IFCC reference method has emerged, defining HbA1c as Hb that is irreversibly glycated at one or both N-terminal β-chain valines. To calibrate the reference method, after isolation from human blood, pure HbA1c and pure hemoglobin A0 are combined in predefined proportions from the certified primary reference material set that is used to calibrate the primary reference measurement system. Two reference methods measure the N-terminal β-chain peptides: in step one, hemoglobin is cleaved into peptides by the enzyme endoproteinase Glu-C; then in the second step, the β-chain glycated and nonglycated N-terminal peptides are separated and measured via HPLC. The reference method values are assigned to secondary reference materials (e.g. whole blood). On incubation with the enzyme endoproteinase Glu-C, the N-terminal hexapeptide of the β chain is cleaved off and glycated and nonglycated hexapeptides are separated and quantified by HPLC plus either electrospray ionization mass spectrometry or capillary electrophoresis with UV-detection (both give identical results). HbA1c is then measured as the ratio between the glycated and non-glycated N-terminal peptides, and is verified via calibration [34,39,72]. Studies comparing the results from the network of laboratories using the IFCC reference method show an ideal intra-laboratory coefficient of variation (CV) of 0.5–2% and inter-laboratory CV of 1.4–2.3% [34].

Methods based on charge difference
Ion-exchange chromatography and high performance liquid chromatography (HPLC)
Ion-exchange chromatography, the most commonly used technique, is essentially based on the method of Trivelli [73]. The original method was laborious and time-consuming, and required the use of large columns and volumes of elution buffers containing cyanides, as well as very stringent control of pH and temperature [74]. The newer assays utilize microcolumns and temperature control column jackets and offer the advantage of speed and relative ease of handling [75]. Kits have been commercially available for some time which contain prepackaged columns with prepared buffers, standards, and additives to eliminate Schiff bases (labile component). Commercial minicolumns are capable of measuring either HbA1 or HbA1c.

HPLC also uses a principle of charge separation of HbA1 or HbA1c from HbA0 but with much greater resolution and speed that lends the technique to automation. Some of the commercial HPLC systems have automatic samplers with a capacity to load up to 100 samples and an analysis time of only a few minutes per sample [76–78].

Isoelectric focusing and agar gel electrophoresis
Since the isoelectric difference between HbA1c and HbA0 is only 0.01–0.02 pH units, conventional electrophoresis is not capable of resolving HbA0 and HbA1c [79]. Isoelectric focusing using a thin-layer polyacrylamide gel containing ampholyte over a pH of 6–8 can resolve these species, but is prohibitively expensive for clinical use [80,81]. Of this group of techniques, electroendosmosis is more commonly used. This method employs agar gel plates with a citrate buffer; the gels are analyzed by scanning densitometry and are capable of differentiating HbA1 from HbA0 in the clinical laboratory setting [82,83].

Methods measuring total glycated hemoglobin
Weak-acid hydrolysis
This method relies on the ability of weak acids to release ketoamine from GHb and convert it to 5-hydroxymethyl furfural (5-HMF) [84]. The amount of 5-HMF can be determined colorimetrically after reaction with thiobarbituric acid. The initial methods had a number of disadvantages, including difficulty in achieving a complete hydrolysis, breakdown of 5-HMF, interference by glucose in the colorimetric assay, and other problems, but further technical modifications have been made to circumvent these shortcomings [85]. Although virtually every step in the method can be automated, the method is not widely used for clinical purposes.

Affinity chromatography
The principle of this method lies in the affinity of boronic acids for the cis-diol groups of glucose and on the reversibility of the reaction in aqueous solutions [86]. The commercially available systems based on this principle employ prepacked affinity columns that contain *m*-aminophenylboronic acid immobilized on either crosslinked beaded agarose [87,88] or Sepharose [89]. The GHb is retained on the columns, while the nonglycated hemoglobin passes through. In the next step the retained GHb is eluted from the column with a buffer containing a competing ligand such as sorbitol. Although it has been shown that a small proportion of GHb is not retained on the column [90] and the assay is sensitive to temperature change [91], the overall variation of replicate samples has been reported to be below 3%.

Method based on immunoassay
An immunoassay for HbA1c has recently become available [92]. The method, which is based on microtiter plate technology, utilizes a mouse monoclonal antibody raised against an epitope that consists of the ketoamine linkage plus the first eight amino acids of the N-terminal end of the hemoglobin β chain. The precision of this method is quite acceptable and the within-batch and between-batch coefficients of variation are equal to or less than 5%. One point to note is the low range of reference values (2.8–4.8%). The HbA1c values determined by the new immunoassay correlate well with other standard methods of HbA1c measurement, including HPLC. Since the antibodies used are specific for the underlying molecular structure of HbA1c, the immunoassay does not detect glycation of other hemoglobin variants, although samples should be treated to remove the labile component (Schiff base), since this can cause falsely elevated test results.

Frequency of HbA1c testing

HbA1c is thought to reflect average glycemia over the preceding few months [2] and has been demonstrated in multiple trials to be predictive of risk of diabetes complications [33,68]. Therefore, the ADA recommends that HbA1c testing be performed at least twice a year in patients who have stable glycemia and have met their glycemic goal, and quarterly in patients not at goal or in those who have had recent therapy changes. More frequent HbA1c testing may be necessary in patients who must be intensively managed, such as pregnant type 1 diabetic patients. Point-of-care HbA1c testing may be used for more timely monitoring [43].

HbA1c testing affected by comorbid illnesses

Hemoglobinopathies

There are a number of potential pitfalls in the use of HbA1c in the presence of a hemoglobinopathy or other complicating illnesses affecting the erythrocyte lifespan, such as hemolytic anemia (recently reviewed by [92,93]). In some clinical situations, commonly used clinical assay methods may yield false values (Tables 59.2 and 59.3). Understanding the methodology currently used by the practitioner's clinical laboratory is essential to the proper interpretation of the test results. Over 700 hemoglobin variants are recognized worldwide; and some, like HbS, are common, affecting up to 9% of African Americans [94]. Since the presence of hemoglobinopathies can markedly affect HbA1c test results, close attention should be paid to the interpretation of laboratory results in this setting. Bry et al. [95] have recently reviewed the effect of hemoglobin variants on glycohemoglobin testing and provided practical guidelines for test

Table 59.2 Conditions affecting measurement of GHb levels by chromatography

- Increase measured levels
  - Negatively charged hemoglobin variants
  - Uremia (carbamylation of Hb)
  - Alcoholism
  - Lead poisoning
  - Elevated triglycerides
  - Iron-deficiency anemia
  - Post-splenectomy
  - Hyperbilirubinemia
  - Opiate addiction
  - Chronic aspirin therapy
- Decrease measured levels
  - Positively charged hemoglobin variants
  - Hemolytic anemias
  - Acute or chronic blood loss
  - Pregnancy

applications and interpretation. If the HbA1c testing does not roughly correlate with the patient's own monitoring of capillary blood glucose, the possibility of an underlying hemoglobin variant or disorder of erythrocyte stability should be explored. When dealing with populations in which HbSS, HbCC, or HbSC diseases are common and in which glycohemoglobin determinations have limited utility, laboratories should offer alternative forms of testing, such as glycated serum proteins or glycated serum albumin (discussed later). Physicians taking care of patients with diabetes should especially be aware of hemoglobinopathies that may be prevalent in their patient populations. A list of appropriate assays can be found at http://www.ngsp.org/interf.asp.

HbF comprises 70% of the total hemoglobin at birth and falls to less than 1% in adults. In some individuals with hereditary persistence of HbF, its concentration can reach up to 30% of total hemoglobin, while in patients with β-thalassemia and sickle-cell anemia, HbF can comprise from 2–20% of the hemoglobin level [94]. Most boronate affinity column techniques separate HbF and GHb from HbA and HbA1c and provide accurate measurements of GHb; the immunoassay method and cation exchange, may show erroneous values [95]. Similarly, with HbS disease and trait, the boronate affinity method is the best assay to use (Table 59.3). In patients homozygous for sickle-cell anemia, interpretation of HbA1c requires caution, given the pathologic processes, including anemia, short red cell lifespan, and transfusion requirements. An alternative reference range may be used to correct for the shortened lifespan of red cells in HbS patients [96]. Additional measurements of glycemic control such as glycated serum albumin, should also be considered in these patients (see later).

HbC trait has a prevalence of 2.3% among African Americans and a false increase has been shown even with a boronate affinity method [95]. The use of an altered protocol on certain analyzers may fully separate HbC from HbA for accurate reading [97]. Calculation of mean blood glucose and use of fructosamine assay (see later) may be an alternative in these conditions to assess long-term control.

HbE trait is the most commonly encountered hemoglobin variant in Southeast Asia with a prevalence of up to 30% in the indigenous population [98]. Most of the cation exchange chromatographic methods will report falsely decreased values whereas boronate affinity methods and immunoassays are free of error in such cases. Again, a reduced erythrocyte lifespan and increased turnover of red blood cells needs to be considered in affected cases, which will impact the time span of the HbA1c estimate of mean glycemia.

Uremia

HbA1c levels have been found to be less reliable in renal failure because uremia per se has effects on HbA1c level independent of a change in blood glucose level. Urea present at high levels in patients with renal failure may dissociate in the circulation to form cyanate. Protonation of cyanate leads to formation of

Table 59.3 Effects of frequently encountered hemoglobin variants on measurement of GHb

Variant or derivative	Method		
	Cation exchange	Immunoassay	Boronate affinity
Carbamyl-Hb	Increase typical	NC*	NC
HbAS	NC or increased	NC or increased	NC
HbAC	NC	NC or increased	NC or reduced
HbAE	Falsely low or new reference range needed	NC	NC
HbSS	Unsuitable	May be OK with new reference range	NC or new reference range needed
HbCC	Unsuitable	May be OK with new reference range	NC or new reference range needed
HbSC	Falsely low or unsuitable	NC	NC
Increased HbF	Falsely low or unsuitable	NC or false readings	NC

*NC = no change.

isocyanic acid, which condenses with the N-terminal amino groups of hemoglobin in a process similar to glycation to form carbamylated hemoglobin [99]. Uremic patients may have carbamyl-Hb concentration as high as 3% of total Hb. Carbamylated hemoglobin tends to comigrate with HbA1c in assays separating HbA1c based on its electrical charge (cation-exchange chromatographic techniques) to give falsely high levels. This phenomenon only affects charge-dependent assays, such as column- and ion-exchange chromatography and agar gel electrophoresis, and the interference is only significant when serum urea levels are greater than $84\,\mathrm{mg\,dL^{-1}}$ $(30\,\mathrm{mmol\,L^{-1}})$ [100]. Immunoassay methods and boronate affinity columns to detect HbA1c are more reliable in uremic patients [95].

HbA1c levels also may be elevated in patients with renal failure because of an increase in rate of HbA1c formation, possibly as a result of uremic acidosis. Some analyzers, for example the A1c 2.2 HPLC analyzer, can apparently measure HbA1c accurately in uremic patients [101]. While HbA1c in the range of 6–7% may be estimated accurately in patients with severe renal impairment, values above 7.5% may overestimate the degree of hyperglycemia in patients with severe renal insufficiency [102]. These confounding factors arising from ion-exchange techniques can be avoided by use of boronate–agarose affinity chromatography or a thiobarbituric acid method, both of which can be used reliably in end-stage renal disease, but are time-consuming for routine determinations [103].

Overall, a boronate affinity chromatography method is the method of choice in the setting of hemoglobin variants and end-stage renal failure; however, affinity columns are unable to correct for the reduced lifespan of erythrocytes due to hemolysis or erythrocyte fragmentation. Clinicians also need to be aware of the changes in erythrocyte lifespan occurring during rapid blood loss or initial treatment with iron, folic acid, or vitamin B12 of the respective deficiency anemias [104].

Other metabolic conditions

The presence of an elevated bilirubin or hyperlipidemia interferes with certain HbA1c assays, especially in situations when whole blood is used rather than an erythrocyte hemolysate [26]. Marked hypertriglyceridemia, hyperbilirubinemia, opiate addiction, lead poisoning, alcoholism, and long-term treatment with large doses of aspirin may spuriously elevate HbA1c measurements when determined by cation-exchange chromatography [105]. It has also been shown that vitamin C in doses of 1.0 gram daily for 3 months decreases HbA1c as measured by affinity chromatography by about 20%, while it increased HbA1 determined by agar-gel electrophoresis by 16% [106,107].

Glycation of serum proteins

The measurement of blood glucose is the *sine qua non* for the detection, treatment, and monitoring of the progression of diabetes. The discovery of nonenzymatic glycation of hemoglobin, discussed earlier, paved the way for the possibility that other proteins could also be derivatized by glucose and serve a possible role as a measure of glycemia over time. Similar to hemoglobin, serum and intracellular protein molecules are subject to nonenzymatic glycation to form stable ketoamines, or fructosamines [108]. Fructosamine is the standard name for 1-amino-1-deoxy-fructose, also called isoglucosamine by Emil Fischer, who first synthesized the compound in 1886. The glycation of albumin accounts for approximately 90% of glycated serum proteins [109]. Glycation of serum proteins is similar to that of hemoglobin, except serum proteins do not contain β-amine terminals; therefore, attachment of glucose occurs at the ε-amino groups of lysine side chains [110]. Consequently, charge-dependent methods, like those used to separate HbA1c from HbA, cannot be used to measure fructosamine.

The rate of stable ketoamine formation is four to five times faster in glycated serum proteins than in hemoglobin [111]. Fructosamine reflects integrated glycemia during a period of 2–3 weeks, reflecting the half-lives of the derivatized serum proteins [112]. Use of the fructosamine assay has been well documented in clinical settings like hemolytic anemias and hemoglobinopathies where measurement of HbA1c by conventional techniques may not provide a reliable index of glucose assessment (discussed earlier). For this reason, measurement of fructosamine has been on the rise especially in the developing world where significant numbers of patients have anemia and abnormal hemoglobin. In addition, fructosamine testing may be very helpful in patients with chronic renal failure who have increased levels of carbamylated hemoglobin, which can affect the clinical HbA1c measurement assay [93]. However, falsely low fructosamine values in relation to mean blood glucose values will occur with rapid albumin turnover as occurs in patients with protein-losing enteropathy or nephrotic syndrome [93].

Assay methods for glycated serum proteins

In 1982, the fructosamine assay was developed and became commercially available [113]. To date, reduction of nitroblue tetrazolium dye (NBT) has been the most common method to estimate glycated serum proteins (fructosamine). It is a colorimetric test that is based on the ability of fructosamines to act as reducing agents in alkaline solution and convert NBT to a purple dye that can be monitored by absorbance at 530 nm. As with any other biochemical method, fructosamine assays have their limitations [114]. A number of problems have been found with this original automated fructosamine assay, such as standardization difficulties [115], lack of specificity [116], and interference by lipemia and urate [117,118]. Of course, fructosamine values are affected by low serum albumin and plasma proteins, as in cases of protein-losing nephropathy or liver failure, and must be interpreted with caution under these circumstances.

A variety of biochemical methods have been developed for fructosamine [119,120]. In the early 1990s, Boehringer–Mannheim and Roche Diagnostics developed an improved fructosamine assay [121], with reduced protein matrix effects and less interference by lipemia and urate. More recently, a nonseparation fluorescence-quenching assay for the measurement of total glycated serum proteins has been introduced [122]. The principle of this method is that the fluorescence of a fluorophore, a boronic acid derivative, is quenched when it is bound to glycated proteins but not when it is unbound. The drop in fluorescence is proportional to the concentration of glycated protein.

Clinical usefulness of fructosamine analysis in diabetes mellitus

Fructosamine assays may be used in clinical settings to detect short- to medium-term changes in mean blood glucose. Fructosamine assays also assist in certain clinical conditions where measurement of HbA1c is considered less reliable. The half-life of hemoglobin is approximately 60 days, of albumin 14–20 days, and that of various other proteins, 2.5–23 days. In a group of diabetic patients treated to achieve better glycemic control, the concentration of glycated albumin entered the normal range and plateaued, while the concentration of HbA1c continued to fall [123]. This study showed that the kinetics of the fructosamine test differ from those of the HbA1c, and that it might serve as a more sensitive indicator of average blood glucose over a shorter time frame.

Austin et al. [124] showed that measurement of fructosamine could be a useful adjunctive test for management of outpatients with diabetes in situations where it is not practical to obtain same-day glycohemoglobin concentrations. This study also proved useful for patients less compliant with home glucose monitoring, or where recent changes in insulin dose or clinical presentation might not be reflected in the HbA1c levels. Weekly home testing of fructosamine, combined with therapeutic interventions based on the results, has also been found to lead to a more rapid and significant improvement in glycemic control than did a conventional regimen of testing based solely on capillary glucose testing [125].

The correlation between predicted HbA1c and fructosamine was fair ($r = 0.88$) in diabetic patients but not in control subjects ($r = 0.01$) [126]. Other studies have questioned whether there is any additional benefit gained from measuring the fructosamine in the course of clinical monitoring of patients with diabetes that cannot be obtained from measuring capillary glucose or HbA1c [127,128]. A recent study has substantiated that HbA1c measurement correlates better with home capillary blood glucose levels than with the fructosamine assay, even over the previous 2–3 weeks [125]. The most commonly cited problem confounding the interpretation and reliability of such data is related to short-term fluctuations in serum protein levels observed in diabetic patients [129,130]. Thus, although tests such as the fructosamine assay are relatively inexpensive and simple to perform, they have been questioned as a reliable index of hyperglycemia. Accordingly, fructosamine is not sufficiently sensitive or specific to be used as a screening tool for the diagnosis of diabetes. Although similar conceptually, fructosamine and GHb are two very distinct tests with different reference ranges ($170–285 \, \mu mol \, L^{-1}$ in a nondiabetic patient, and 0.6–3.0%, respectively) [131,132].

Monitoring of glycemia in pregnancy

Measurements of HbA1c are recommended with greater frequency during pregnancy with preexisting diabetes. The ADA specifically recommends a DCCT-referenced assay performed at the initial visit, monthly throughout pregnancy until target levels of <6.0% are achieved, and then every 2–3 months [133]. However, although subject to the potential confounding influences of variations in serum protein concentration,

glycated serum protein measurements may be conceptually more appropriate than HbA1c given the time constraints of normal gestation and the desire to maintain near-normal glycemia over short-term periods. Because of changes in the distribution of body water, a significant decrease in serum albumin and serum fructosamine concentration occurs during normal pregnancy [134]. In spite of this, the value of short-term monitoring of glycemic control has been substantiated in a few studies [135,136]. In general, the use of glycated serum protein assays in diabetic pregnancy cannot be used to replace the frequent monitoring of capillary glucose levels, but perhaps as a verification of the overall level of glycemic control that may lead to alterations in the treatment plan if the glycated proteins begin to increase with monitoring every 3–4 weeks [137].

1,5-Anhydroglucitol as a measure of glycemia

1,5-Anhydroglucitol (AHG) is a polyol mostly derived from ingestion that is competitively excreted with glucose by the kidneys. As glucose levels rise, the amount of AHG decreases. After extensive studies and use in Japan and subsequent studies in the US, AHG testing was recently approved by the FDA for clinical use (GlycoMark™). AHG is emerging as a marker of glycemia that responds more readily to glucose trends than HbA1c, and also offers the advantages of a simple blood test that is metabolically stable and shows small biological variability [138]. AHG may be a more valid predictor of the risk of diabetes complications than fructosamine, but this remains to be proven. Also, available US studies have excluded patients with renal disease, and AHG may be unreliable in these patients. US studies show that serum AHG reflects glucose levels over the prior 48 hours to two weeks, and demonstrates good concordance with HbA1c and fructosamine levels and agreement with 20 years of previous Japanese studies [138–140]. Changes in AHG with changes in glucose are also more significant than with fructosamine in these studies. McGill et al. propose AHG as an appropriate interim marker for use between 3-month HbA1c measurements to help patients modify behaviors before complications occur [138]. AHG may also be a good indicator of postprandial hyperglycemic excursions. Finally, Sone et al. advocate for the use of AHG to identify patients at risk for future uncontrolled hyperglycemia and diabetic complications [141].

Advanced glycosylation end-products and diabetic complications

Multiple mechanisms have been described by which chronic hyperglycemia may contribute to the pathological end-organ complications that occur in diabetes mellitus. These include direct effects of elevated glucose on cells, hyperosmolality, oxidant stress, and nonenzymatic glycosylation. The irreversible

ketoamine linkage that follows Schiff base formation of glycated proteins can undergo a series of multistep reactions potentially along several different pathways (Figure 59.3). Some of the formed products involve fragmentation to form deoxyglucosones, which may then lead to additional protein cross-links [143,144]. The deoxyglucosones can form highly reactive dicarbonyl compounds that cyclize to form electrophilic pyrrole intermediates and more advanced cross-linked fluorescent derivatives [4,93,145]. The complex biochemistry of the AGEs and the implication of the formation of these derivatives *in vivo* is incompletely understood, and remains an area of active research.

Once formed, AGE-protein adducts, such as carboxymethyllysine (CML) and pentosidine are biochemically irreversible and remain quite stable in the body. AGEs are a heterogeneous family of biochemical end-products of nonenzymatic glycosylation. Circulating human AGE peptides are of variable size (molecular weight between 2000 and 6000) and characterized by intra- or intermolecular cross-linking products with cyclic aromatic rings that convey fluorescence [93]. In addition to their chemical reactivity, some AGE structures, for example N-carboxymethyllysine [146], lead to the formation of antibodies *in vivo* [147], which may portend an additional mechanism for tissue damage. AGE modification of proteins is potentially involved in the normal aging process as well as in the pathogenesis of diabetic nephropathy, atherosclerosis, diabetic retinopathy, and chronic renal failure [148–152].

An additional element of complexity in the effects of AGE products has been the discovery of a specific AGE receptor, called "RAGE," on a variety of cell types including macrophage/monocytes [153] and endothelial cells [154]. The AGE receptor may transmit effects of AGE products on signal transduction that may mediate its detrimental effects in tissues [154–156].

The discovery of RAGE has led to the development of a whole-cell radioreceptor assay for AGEs [157]. The principle of this assay rests on the assumption that the family of AGEs have similar affinity for the AGE receptor, and that those present in the sample will compete, in proportion to their concentration, with the binding of labeled AGE-modified albumin. The amount of AGEs in the sample is read from the standard curve showing competition binding of labeled and unlabeled AGE-modified albumin, and expressed in units defined as amount of the test protein required to inhibit the binding of 50% of the labeled AGE-modified albumin [157]. With this assay it is possible to detect AGEs in serum both in normal and diabetic patients. In the first report of its kind it has been documented that serum AGEs of molecular mass <10 kDa in nondiabetic patients with end-stage renal disease are increased 1.5-fold compared to those in normal individuals, and increased fivefold in patients with end-stage renal disease and diabetes [158]. This study raises two important questions, and the answers remain uncertain. First, do the AGEs themselves contribute to the development of chronic complications seen in diabetes? The authors of the cited
Figure 59.3 Formation of advanced glycosylation end-products from glucose. *N*-glucosylamine is a reversible Schiff base product and the Amadori rearrangement leads to the formation of 1-amino-1-deoxyketose. The production of these reversible early products can give rise to irreversible advanced products through generation of highly reactive carbonyl compounds such as 3-deoxy-D-glucosone. Source: Brownlee 1992 [142]. Reproduced with permission of the American Diabetes Association.

report suggest that the AGEs in the serum (especially those of low molecular weight) are metabolites of AGE-modified proteins formed in the tissues. The major route of elimination of these metabolites, especially those of molecular weight of <10 kDa, is through the kidneys, and the progression of renal failure leads to their retention in serum. The several-fold increased retention of low-molecular-weight AGEs in patients with end-stage renal disease and diabetes compared to the other study groups indicates that the turnover of AGEs in diabetes is greatly increased. Moreover as shown by the authors [158], the serum AGEs are poorly dialyzable and may contribute to the rapid progression of complications and mortality of patients with diabetes requiring dialysis.

At present, monitoring of serum AGEs remains a research tool that is not widely available. In the next few years, progress in this area of research may provide a new dimension in the clinical monitoring of diabetes and its complications that can extend the value of measurement of glycated proteins far beyond their present applications. A number of potentially therapeutic compounds are under extensive study in animals and humans for potential use in diabetics, in an effort to eliminate the accumulation of AGE products or minimize the deleterious effects of AGE [93]. Current early-stage research indicates that inhibition of AGE formation and receptors for AGE (RAGE) may represent possible therapeutic endpoints for new therapies to treat diabetic retinopathy [159].

Artificial pancreas

The advent of the continuous glucose monitoring (CGM) device, which measures glucose in the interstitial fluid at least 288 times daily, has made possible the concept of the "artificial pancreas" when linked with previously developed insulin pump technology for continuous subcutaneous insulin infusion (CSII) (or in a bihormonal system with insulin pump plus glucagon pump for counterregulation) that is controlled by a computer-run insulin delivery algorithm. The premise of the artificial pancreas is the use of a closed-loop system to eliminate SMBG, monitoring with surrogate markers such as HbA1c, and self-adjustment of insulin [160], while concurrently helping diabetic patients reach previously elusive near-normal HbA1c levels with fewer extremes of hypo- and hyperglycemia and diabetic complications [161]. In other words, the artificial pancreas would attempt to replicate the functioning of the β cells of the pancreas of a person without diabetes. Additionally, the artificial pancreas would obviate the need for available pancreas or islet cells for transplantation, immunosuppression for those transplantations, and dependence on the long-term functioning of a transplant [161]. Two main approaches to the closed-loop system have been described in the literature: extracorporeal (with both subcutaneous glucose monitoring and insulin delivery) and implantable (with intravenous sampling and intraperitoneal insulin delivery). Both of these approaches have been shown to be attainable in the laboratory setting and with use of a model predictive controller [162]. Limitations to use in the home setting include reliability and accuracy of CGMs, unwieldy implanted systems and need for continuous intravenous access, regulatory difficulties, and disagreement over extracorporeal versus implantable approach as well as associated insulin delivery calculation algorithms [162]. A particular challenge involves estimation of pre-meal boluses without information as to meal size or timing in a fully closed-loop system. Revisions involve inclusion of meal size and meal timing information in a semi-closed-loop approach, or timing but not size of the meal in a so-called "closed-loop with qualitative meal announcement approach" [162], with most closed-loop systems appropriating one of the first two approaches.

Current studies have utilized *in silico* design for regulatory approval via the FDA, using computer-based simulations on virtual subjects as a substitute for animal trials, allowing for simulation of any open- or closed-loop scenario prior to testing in human subjects [163]. Multiple studies have shown that the amount of time that BGs remain in the prescribed

target ranges increases with closed-loop delivery in human subjects [163,164]. Model-predictive control with utilization of *in silico* design may soon allow for the institution of a truly viable closed-loop system without need for patient-based SMBG or monitoring of serum markers for control of blood glucose.

Acknowledgments

The authors are grateful to Drs. Jerzy Kolaczynski and Barry Goldstein for their contributions to the writing of previous versions of this chapter.

Complications of diabetes: general and microvasular

Pathogenesis of diabetic microvascular complications

Josephine M. Forbes[1] and Brooke Harcourt[2]

[1]Cardiovascular and Metabolic Diseases Mater Research Institute, The University of Queensland, Brisbane, QLD, Australia

[2]Mater Research Institute- UQ, TRI, South Brisbane, QLD, Australia; Mater Clinical School, University of Queensland, Brisbane, QLD, Australia

Key points

- Glycemic control is a major determinant of progressive microvascular complications.
- Microvascular complications and glycemic control should not be viewed as mutually exclusive when considering therapeutic options.
- Despite different clinical manifestations probably common pathogenesis of disease at unique sites of microvascular disease.
- Common accelerators include blood pressure, abnormal lipid profiles, obesity, gender, age.
- Logical to study patterns seen in all microvascular complications, rather than one disorder in isolation.
- Pathogenic pathways directly affected by altered glycemic control—most logical therapeutic targets.
- Should consider outcomes of therapies for all microvascular complications when considering their effectiveness.

Introduction

The development of chronic vascular complications is common in individuals with both type 1 (T1) and type 2 diabetes (T2DM). These are in general, divided into micro- and macrovascular complications, with the most prevalent microvascular complications being kidney disease, blindness, and amputations. Given the morbidity and mortality associated with these complications, there is a significant treatment gap, with current therapies only slowing disease progression. In addition, a number of large-scale clinical trials have in general yielded disappointing or incremental results with respect to the benefits of current treatments. One fundamental observation, however, in clinical studies, is that early strict glycemic control can radically reduce the incidence of microvascular complications and that this is further enhanced by addressing abnormal lipid profiles and hypertension. The benefits of improved glycemic control are less consistent with respect to macrovascular disease, where large-scale clinical trials in patients with a long duration of diabetes have implied that strict glycemic control may in fact be detrimental in some circumstances. Indeed this suggests that there may be two distinct phases in the development of diabetic complications.

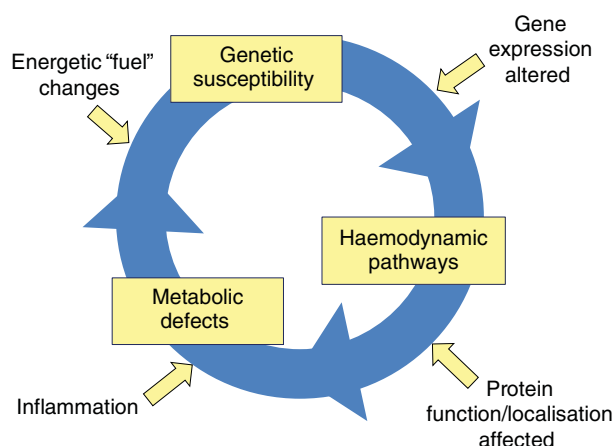
Therefore given the clear association between strict glycemic control and microvascular disease in diabetes, it seems that more careful consideration of the consequences of poor glycemic control on the microvasculature of the kidney, nerves, and retina is warranted. As a consequence, pathologic pathways uniquely activated by hyperglycemia at sites of microvascular disease have gained much attention in previous preclinical studies. Perhaps our mistake, however, is to consider progressing only those therapies that work independently of effects on glycemic control, when it may be that the two are intimately intertwined. In addition, residual pancreatic C-peptide secretion is a common feature in patients who have not developed significant microvascular complications of diabetes despite having had T1DM for more than 50 years (such individuals are known as medalists), which also suggests a relationship between preservation of islet function and the lack of progressive microvascular complications which is independent of HbA1c concentrations. Furthermore, there may be demonstrable value in identifying common pathways activated by hyperglycemia at sites of diabetic complications [1] and differentiating these from tissue/organs sites which appear less susceptible to hyperglycemia. Each of these concepts will be discussed within this chapter as we outline common pathogenic pathways (Figure 60.1) which may play causative roles in diabetic microvascular complications.


Figure 60.1 Overview of the interdependent contributors to diabetic microvascular complications.

Gene regulation

Can our tissues remember?

The contribution of hyperglycemia per se to the complications of diabetes needs to be further investigated given the relatively disappointing findings from the ACCORD and ADVANCE clinical trials, which explored the effects of strict glycemic control in type 2 diabetic subjects with established cardiovascular disease (described in Chapter 42). On one hand, it could be that a lack of effect on cardiovascular mortality relates to the relatively short duration of the trials, but equally plausible is that irreversible vascular changes have occurred prior to the trial, such as may be imparted by biochemical reactions, for example advanced glycation. The first suggestion of this is from some elegant studies performed in diabetic dogs with retinopathy more than 20 years ago [2], which showed progression of retinal disease despite good glycemic control.

This is now postulated to be the result of hyperglycemic memory or a legacy effect where the body remembers previous episodes of either good or poor glycemic control. The most likely explanation for this phenomenon, termed "metabolic memory," is an epigenetic mechanism involving glucose-induced effects on histone modifications leading to modulation of vascular gene expression [3,4] which persists despite a return to normoglycemia. Metabolic memory has been observed in a number of large clinical trials where early intensive glycemic control has a sustained impact on reducing the risk of subsequent diabetic microvascular complications. These effects are evident well beyond study completion and the time when there were changes from strict to more conventional glycemic control. In the DCCT where both strictly and conventionally controlled patients were followed (described in Chapter 41) the benefits of strict glycemic control persisted for another 10 years in the EDIC study (Chapter 41) on microvascular endpoints. Metabolic memory has also been described in cultured cells

[3] and in animal models showing that islet transplantation cannot prevent retinopathy progression beyond a certain time point [2,5,6]. It is still unresolved as to what is the specific cause of metabolic memory. One promising candidate is the programming of a reversible epigenetic memory effect on cells via good glycemic control.

Histone modifications

There are two major processes which contribute to the remodeling of chromatin, a complex of DNA and histone proteins. First, posttranslational modifications of the histone tails via acetylation, methylation, advanced glycation, ubiquitylation, and phosphorylation can occur in diabetes at sites of microvascular disease [7,8]. Second, DNA can be directly altered via modulating methyl groups within CpG sites. Ultimately, the role of these processes is to allow or to prevent the unwinding of DNA to manipulate the exposure of specific gene sequences. These effects may be heritable and thus are able to be passed through many cell divisions.

Acetylation of histones is a dynamic process regulated by two opposing families of enzymes, histone acetyltransferases (HATs), which are responsible for histone lysine acetylation resulting in "opening" of the DNA to allow for transcription factor and RNA polymerase II binding, while histone deacetylases (HDACs) remove lysine acetylation and repress gene transcription [7,8]. Indeed, glucose concentrations are known to alter histone acetylation.

Methylation of histones at lysine and arginine residues, although also a dynamic process, is thought to impart longer lasting changes which lead to both repression and activation of gene transcription. Protein arginine methyltransferases (PRMTs), are commonly involved in gene regulatory events via mono- or dimethylation of arginine residues [7,8]. At lysine residues, methylation is often complex given that they can be mono-, di-(me2), or trimethylated. Lysine demethylases (HDMs) can also alter gene expression emphasizing the bidirectional nature of histone methylation [7,8]. DNA methylation also changes in response to transient hyperglycemia.

A number of changes in expression and activity of histone deacetylases (HDAC), histone methyl transferases (HMTase), histone acetyl transferases (HATs), and histone demethylases (HDMs) have been identified at sites of diabetic complications. Most of these studies have been performed in endothelial cells, where changes in these enzymes have been associated with the regulation and transcription of specific genes including the NF-κB subunit, p65 [3]. Preclinical studies in leukocytes including monocytes from diabetic patients have exhibited epigenetic modifications including changes in effects on histones such as H3K9me2 and H3K4me2, which are associated with immune and inflammatory pathways [7,8]. In addition, TGF-β1 treatment of renal mesangial cells increases the histone methyltransferase, SET7/9, which is associated with the expression of profibrotic genes in these cells [7,8].

Reversal of epigenetic memory, or epigenetic therapy, has gained interest for the treatment of diabetic complications. Indeed, curcumin (a derivative of turmeric), which is an inhibitor of histone acetyl transferases, can lower the expression of a number of inflammatory genes and has shown promise in the treatment of diabetic nephropathy in both humans and in experimental models of diabetes [1].

Other approaches targeting epigenetic regulation in experimental models of diabetes [7,8] have also shown promise. Furthermore, it is likely that these compounds may be useful for the treatment and prevention of atherosclerosis and retinal neovascularization given previous beneficial effects seen in the nondiabetic context with respect to these disorders [1].

MicroRNA

MicroRNAs (miRNAs) are short sequences of RNA, which can manipulate the translation of messenger RNA via interaction with complementary sequences located within the 3′ untranslated region. MicroRNAs are transcribed from sequences contained within the "noncoding" introns of DNA and play important roles in regulating gene expression.

The diabetic kidney has received the most scrutiny with respect to miRNA expression and effects. Not surprisingly, most of this research has focused on miRNAs that target molecules involved in renal fibrosis via effects elicited by TGF-β1 such as miR-192 which is thought to target and repress zinc finger E-box-binding homeobox 2 (ZEB2), affecting changes in deposition of type 1 collagen, most likely via repression of Smad7 signaling [9]. This has also been shown in other renal diseases. A number of other miRNAs are also implicated in the accumulation of extracellular matrix in organs effected by diabetes, including miR-21, miR-29, miRNA-216a, miR-377, and miRNA-93 via regulation of a number of TGF-β stimulated molecules [9]. In addition, protection against the accumulation of collagen I and fibronectin and decreases in VEGF expression have also been shown in the diabetic kidney and retina by the miRNA 200 family [1,10,11].

Hyperglycemia—too much fuel or not enough?

The chronological sequence of events which ultimately results in a decrease in cellular energy production, despite excess fuel (glucose and lipids) availability, is not well understood in diabetes. It is widely postulated that cells within tissues that are prone to diabetic complications have difficulties modulating glucose transportation and metabolism. Initially, changes in the diabetic milieu alter energy production in these cells by increasing concentrations of intracellular glucose-derived metabolites. Eventually, this progresses to impairment of cellular energy production by inhibition of energy substrate delivery to cells because of cellular compensatory mechanisms such as insulin resistance. However, this ultimate loss of ATP content within complication-prone tissues is considered to occur relatively late in the development of the disease and postulated to be responsible for the end-organ dysfunction and cell death [12]. Conversely, however, it is plausible that changes which actually enhance energy production from excesses in substrates such as glucose in particular, are more likely early pathologic events in the development of complications. It is possible to hypothesize therefore, that modulating glucose delivery into tissues thereby preventing the switching of cells to inappropriate fuel sources is likely to be another reason as to why glycemic control appears effective in lowering the risk of microvascular complications.

Unfortunately, optimization of glycemic control in T2DM requires therapeutically complex regimens where outcomes of individual agents are often difficult to assess. It has been shown that at least some of the antiglycemic agents exhibit direct benefits on microvascular complications (Figure 60.2). This includes thiazolodinediones, agonists for peroxisome proliferator activated γ receptors (PPARγ agonists) have shown beneficial effects on complications, independent of their glucose lowering through attenuating fibrosis by reducing the production of pro-fibrotic cytokines. The future of this class of agent in diabetes, however, has been overshadowed by data showing increased risk of cardiovascular events with rosiglitazone (see Chapter 40) and increased bladder cancer with pioglitazone as well as other side effects with both agents such as fluid retention, exacerbation of heart failure, and increased bone fractures.

Metformin is more complex, where conflicting effects on the microvascular complications of diabetes, have been identified. As an example, metformin therapy worsens peripheral neuropathy in diabetic individuals, which is postulated to be the result of effects on vitamin B12 (see Chapter 41). It is interesting that detrimental effects of modulating specific vitamin B groups have also been shown in diabetic nephropathy in humans (see Chapter 41). Conversely, other studies have identified beneficial effects on diabetic renal disease with metformin in humans (Chapter 41) and in animal models [1]. In general, these favorable outcomes are thought possibly to be as a result of effects on lipids including free fatty acids (FFA) leading to a less pro-inflammatory profile and reduced oxidative stress.

Analogues that mimic the actions of the insulinotrophic glucagon-like peptide (GLP-1) have been shown to bind to receptors present at sites of diabetic complications [13]. In addition, activation of the GLP-1 receptor using these GLP-1 receptor agonists in diabetes appears to be beneficial for kidney disease, and appears to be mostly independent of changes in glucose homeostasis. GLP-1 receptor agonists also affect sodium handling by the kidney which is another important contributor to development and progression of diabetic complications by modulation of hemodynamic pathways [13].

Another way to increase the amount of GLP-1 within the circulation is to target its metabolizing enzyme, dipeptidyl peptidase IV (DPPIV). DPPIV inhibitors have also been shown to have benefits on diabetic renal disease [13].
Figure 60.2 A representative example of sites at which the metabolic disturbances characteristic of diabetes can affect complication prone cells. AdipoR1/2, adiponectin receptor; GLP-1R, glucagon-like peptide receptor; GR, glucagon receptor; IGF-1R, insulin-like growth factor-1 receptor; IR, insulin receptor.

Glucose metabolism

Glucokinase is part of the hexokinase family and is an important rate-limiting enzyme involved in the transport of glucose into cells across the plasma membrane. Changes in this rate-limiting enzyme have been observed at sites of diabetic complications. Once inside the cell, the first major energy system into which glucose-derived molecules are channeled is glycolysis. Glycolysis is an anaerobic process and there is evidence that this pathway is disrupted in diabetes [12]. Glycolysis, however, is not an efficient way to derive energy from glucose, with only four adenosine triphosphate (ATP) molecules being generated for each molecule of glucose. Hence, our cells shuttle the pyruvate produced from glycolysis into our cellular power stations, the mitochondria, where it is used for oxidative phosphorylation by the mitochondrial respiratory chain generating up to 15 times more ATP per molecule of glucose. FFA and ketoacids, which enter the cell, are also taken into the mitochondria and used for oxidative phosphorylation following beta-oxidation. However, glucose-derived intermediates are the most efficient facilitators of ATP generation and use less oxygen than substances such as FFA and ketoacids and hence are the most common fuels used in cells prone to microvascular complications. Conversely, studies such as ADVANCE, VADT, and ACCORD (see Chapter 42), have shown an apparent lack of effect of glycemic control in preventing the progression of CVD and one could postulate that this is as a result of the high utilization of FFA at sites

of macrovascular complications, although this remains to be determined.

An electrochemical proton gradient is created from energy released from nutrients as electrons, which flow through the mitochondrial respiratory chain. In some circumstances, rather than generating ATP, this group of reactions can be uncoupled, producing heat or stopping ATP production. It is therefore not difficult to imagine how this tightly controlled group of reactions may be affected by diabetes where there is excess substrate availability and profound changes in cellular behavior. It remains to be determined, however, as to why some cells seem more vulnerable to these changes, resulting in microvascular changes that we see characteristically in diabetes. Indeed, changes in energy production are thought to be major contributors to the development of diabetic microvascular complications [12]. Some examples shown to date include altered delivery of substrates, switching of cell-specific fuel sources among glucose intermediates, fatty acids and ketoacids, altered mitochondrial respiratory chain function and uncoupling of the respiratory chain. Dysregulation of the family of proteins that regulate uncoupling has also been previously reported at sites of diabetic complications [12].

Other cellular pathways for glucose metabolism

Once glucose is transported inside the cell, most of it is metabolized via glycolysis, through steps involving the conversion

of glucose-6-phosphate to fructose-6 phosphate. When intracellular glucose concentrations are high, however, glycolysis can divert fructose-6-phosphate step-wise to UDP (uridine diphosphate) N-acetyl glucosamine. N-acetylglucosamine is used for posttranslational modification of proteins within the cytosol and nucleus by single O-linked N-acetylglucosamine (O-GlcNAc) glycosylation (which is discussed in detail later in protein trafficking). These resulting sugar residues can compete with phosphate groups altering gene expression in diabetic tissues [1].

Aldose reductase

Under normal glucose homeostasis, aldose reductase has a physiologic role in detoxification of aldehydes into inert alcohols. Hyperglycemia was shown to increase cellular flux through the sorbitol/polyol pathway more than 40 years ago [14]. Under these conditions, NAD(P)H, delivered from the pentose phosphate pathway, catalyzes the conversion of glucose to sorbitol by aldose reductase rather than altering the flux of glucose into glycolytic pathways. Facilitation of this alternate pathway of glucose flux is thought to contribute to cellular antioxidant inhibition by depleting reduced glutathione and glutathione peroxidase enzymes. Changing cellular concentrations of sorbitol may also provide a source of excess NADH to complex I of the mitochondrial respiratory chain. In addition, intracellular accumulation of sorbitol alters cellular osmolarity exacerbating cellular oxidative stress. In support of this, there is some evidence that diuretics which decrease osmotic stress can protect from cell death in cells exposed to hyperglycemia.

In animal models of diabetic microvascular complications, there has been some success achieved in preventing disease progression using inhibitors of aldose reductase [15,16]. However, this has failed to translate to the clinical context despite decades of active investigation (see Chapter 41).

Impaired insulin signaling

It is widely thought that exogenous insulin therapy as part of more intensive glycemic control can protect against the development and progression of microvascular complications in diabetic individuals (see Chapter 41), although this must be weighed against what appear to be increases in certain cardiovascular risk factors such as weight gain (Chapter 42). What is noteworthy, however, is that in experimental models, intranasal insulin [17] and pancreatic islet transplants show superior protection to other methods of insulin administration. This implies that other factors related to endogenous insulin secretion and trafficking such as C-peptide, glucagon and immune modulation (discussed later) may have important roles in the protection against microvascular complications. This is in line with recent data from the "Joslin 50-year medalist" cohort which also suggests that remnant pancreatic β cells may protect against the development of microvascular complications (Chapter 41).

The cellular loss of signaling in response to the hormone insulin is termed insulin resistance. Despite a large focus on insulin resistance at sites of peripheral glucose uptake such as skeletal muscle, the liver, and adipose tissue, there are many cell types that require insulin-mediated glucose uptake for normal function including sites of microvascular complications. One study has demonstrated that a deficiency in insulin receptor signaling in podocytes of the kidney can induce a disease state reminiscent of diabetic nephropathy even in the setting of normoglycemia [18]. Selective targeting of glucose transporters such as SGLT2 and GLUT-1 in nephropathy has also shown some benefit in experimental models of diabetic renal disease [1].

Experimentally, deficiencies in insulin signaling can be assessed by examining a reduction in serine 473 Akt phosphorylation in insulin-target tissues. It is interesting that a loss of serine 473 Akt phosphorylation has been identified at sites of diabetic complications [18,19] particularly in models of T2DM. Conversely, Akt activity is increased in some tissues and vascular beds affected by complications in T1DM. Whilst it is likely that impairment of Akt activity is preventable with strict metabolic control, the combination of hyperglycemia and insulin treatment results in enhancement of mTOR activity which may also be of benefit (discussed in the Autophagy section later). An adequate explanation for this paradox at sites of diabetic complications remains to be established but may be resolved by evaluation of therapeutic benefits of pharmacologic modulators of Akt activity.

Hemodynamic pathways

We know that there are many factors that contribute to the development and progression of diabetic microvascular complications, including metabolic and hemodynamic factors [1]. The best characterized of these hemodynamic contributors include systemic and tissue-derived components of the renin-angiotensin-aldosterone system (RAAS) which are actively targeted as a major part of clinical care for diabetic individuals who develop microalbuminuria or hypertension (Chapter 41). Although hypertension is often considered a manifestation of diabetic renal disease, it is also an important systemic factor in exacerbating or promoting diabetic microvascular complications.

The renin-angiotensin-aldosterone system (RAAS)

The RAAS is a hormonal cascade that is considered as a body-wide master controller of blood pressure and fluid balance. In concert with these systemic effects, a local tissue RAAS appears to be present at sites of microvascular complications. Clinically, the most widely applied RAAS blockers for microvascular disease in diabetes interrupt the conversion of angiotensin I to angiotensin II (AngII), namely angiotensin-converting enzyme-1 inhibitors (ACE-I), agents

which compete with Ang II for binding to the AT1 receptor, AT1 antagonists (ARB), or drugs that inhibit binding of aldosterone to the mineralocorticoid receptor (aldosterone antagonists). The clinical trials outlining the evidence which justifies the use of these agents in humans are discussed in Chapter 41. In the following, we outline some of the newer aspects of the RAAS which have shown promise in experimental models in combating diabetic complications.

Preprorenin, the active precursor of renin, is synthesized and stored within the juxtaglomerular (JG) apparatus of the kidney cortex. Upon stimulation from sources such as baroreceptors and other endocrine pathways, prorenin is secreted through fenestrated capillaries which elevate renin concentrations within the circulation. Another arm has recently been shown experimentally to contribute toward renin activation and secretion under pathologic conditions in experimental models. This pathway is mediated through changes in succinate uptake and utilization via the GPR91 receptor in the collecting ducts which are located in close proximity to the JG apparatus of the kidney [20]. These studies suggest that targeting GRP91 is beneficial in diabetic nephropathy in addition to the finding that urinary succinate concentrations may be a potential biomarker of disease development.

Renin is the hormone responsible for the cleavage of angiotensinogen to angiotensin I (AngI) and this reaction occurs primarily in the systemic circulation. There are a number of pathways that are thought to influence the secretion of prorenin. These include renal pressure sensors (baroreceptors), endocrine pathways, and intracellular mechanisms which may be independent of systemic blood pressure. It appears that the renin inhibitor aliskiren does have some benefits; however, there is some concern as to the side effects of these agents when they are used in combination with ACE inhibitors or angiotensin receptor blockade. Antagonists of the (pro)renin receptor have also been shown to be renoprotective in animal models.

Most commonly, AngI is cleaved to AngII by angiotensin-converting enzyme-1 (ACE-1), where AngII is arguably the most potent effector hormone of the RAAS exerting direct effects on mean arterial blood pressure and extracellular fluid volume. ACE-1 is localized at a number of sites of diabetic complications and may be regulated renally and hepatically via midkine. Angiotensinogen can also be expressed at many sites of microvascular complications including the kidney. Overexpression of angiotensinogen has been shown to cause tubular necrosis in the rodent kidney. Most of the downstream pathways of local RAAS activation have focused on superoxide as an effector molecule. Angiotensin I can also be hydrolyzed by neutral endopeptidase (NEP) to Ang1-7 and smaller peptides such as Ang1-4. Ang1-7 has been shown to have both vasodilatory and pathologic effects in certain contexts [1].

Aldosterone is a hormone produced by the adrenal glands in response to changes in serum potassium concentrations and angiotensins such as AngII. Intrarenally, aldosterone acts to increase the reabsorption of sodium ions and water in the distal tubule as well as facilitating the release of potassium ions into the urine for excretion, which ultimately results in elevations in systemic blood pressure. An increase in sodium also alters extracellular osmolarity increasing systemic blood pressure. Aldosterone elicits the majority of its effects via ligation to the mineralocorticoid receptor, which is the target of aldosterone antagonists which are both antihypertensive and often diuretic. Inhibition of the actions of aldosterone using inhibitors such as spironolactone exhibits direct renoprotective effects. In addition, beneficial effects of aldosterone antagonism on retinopathy in rodents [21] have been reported. However, the common side effect of hyperkalemia is a major limitation of widespread use of this class of agents in diabetic subjects with nephropathy.

AngII mediates most of its biologic effects via ligation to at least two specific receptor subtypes, the angiotensin type1 (AT1) and angiotensin type 2 (AT2) receptors, which are each widely expressed at sites of diabetic complications. Ligation of AngII to the AT1 receptor seems to have pressor actions including vasoconstriction and activation of the sympathetic nervous system. Not surprisingly, AT1 KO mice tend to have lower blood pressure and are protected against the development of microvascular disease in the context of diabetes [22]. These findings support evidence where AT1 receptor antagonists demonstrated end-organ protection in diabetic complications. The downstream pathways affected by these agents include attenuation of fibrotic cytokine production and extracellular matrix accumulation as well as improved vascular permeability [1].

Although the AT2 receptor shares only 34% sequence homology with the AT1 receptor, these two receptors share remarkably similar affinities for AngII. In general, the AT2 receptor is thought to be fetally expressed at sites such as the developing metanephros which becomes the kidney but is not expressed to a significant extent in adults. There is some controversy as to the role of the AT2 receptor in the development of diabetic microvascular complications. It is postulated that the AT2 receptor appears to act as a functional antagonist to the AT1 receptor via protection against ROS mediated damage. However, there is an increasing body of data to show effects similar to those seen with the AT1 receptor in the context of diabetes. These effects include induction of cytokines such as VEGF and promotion of macrophage infiltration via RANTES and MCP-1.

Obesity and dyslipidemia

Hyperlipidemia changes the uptake of FFA by cells, both by passive diffusion and through protein-mediated pathways, most likely via proteins such as CD36 and members of the fatty acid binding protein (FABP) family. Indeed, changes in the expression of CD36 within the diabetic kidney have been previously reported. In addition, individuals with diabetes have increases in both circulating soluble CD36 (sCD36) concentrations and monocyte expression of sCD36. Studies have also

inferred that serum A-FABP and E-FABP concentrations may be biomarkers for evaluating progressive nephropathy and associated cardiovascular risk in individuals with T2DM.

High-calorie diets are commonly high in saturated animal fat, which via increased gastrointestinal absorption may accelerate diabetic complications. It is also thought that obesity-induced neuropathy can be improved by dietary restriction of fat intake, relevant to diabetic individuals who are obese (Chapter 41). The most obvious effects of decreasing saturated fat intake would be on glycemic control where improved insulin sensitivity and secretion could influence end-organ function at sites of microvascular disease. Other compelling evidence of the role of overconsumption of saturated fats in progressive diabetic complications comes from studies using lipid lowering therapies such as statins and fibrates. There is, however, ongoing controversy as to whether restriction of dietary fat intake has beneficial effects on microvascular disease in diabetes.

The two major classes of lipid-lowering agents target either 3-Hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (statins) or PPARα (fibrates including fenofibrate and gemfibrozil). Statins are thought to have broad-ranging benefits in diabetic individuals, while fibrates have shown inconsistent results with a number of pleiotropic effects such as anti-inflammatory actions, in addition to improving flow-mediated dilatation. Statins have also been shown to have anti-inflammatory effects [23], which are postulated to be due to their capacity to limit the production of isoprenoids which are key downstream mediators of the inflammatory response. Fenofibrates (FIELD) have also been trialed with some success in diabetic retinopathy although it is unclear as to whether the effects of these agents are directly related to lipid lowering (Chapter 41). Indeed, one recent study has shown that the beneficial effects of fenofibrate on retinopathy in mouse models of diabetes are via its PPARα agonism [24]. In other experimental models, there is also some rationale for the use of fenofibrates and statins to treat microvascular complications.

Physical activity has also been shown to have effects on diabetic complications in animal models [25], via a reduction in circulating concentrations of a number of factors including advanced glycation end-products (AGEs), insulin and cytokines. As seen in nondiabetic individuals, regular moderate exercise can improve a number of risk factors relevant to the development of microvascular complications and may be an effective nonpharmacologic approach if compliance issues could be overcome [25].

Adipokines

Adipose tissue is highly secretory, releasing a number of factors which are modulated in response to hyperglycemia and viewed to influence diabetic complications. These adipokines include adiponectin, which is thought to reduce oxidative stress. Circulating adiponectin is also predictive of progressive kidney, retinal, and cardiovascular complications in diabetes. In contrast, however, increases in circulating adiponectin

concentrations have also been shown to correlate with vascular complications in T1 diabetic individuals. In rodent models, elevating adiponectin concentrations attenuates, while prevention of the interaction of adiponectin with its receptors, worsens kidney disease in diabetes [19]. These findings are thought to be as a result of changes in AMP kinase.

Leptin is another adipokine thought to influence diabetic complications. Intravitreal leptin concentrations are increased in individuals with proliferative diabetic retinopathy, while leptin has been shown to stimulate ischemia-induced retinal neovascularization [26]. In addition, deletion of the leptin receptor in mice also results in autonomic neuropathy. Systemically, elevations in leptin concentrations are associated with renal disease and infusion of exogenous leptin leads to renal disease in various experimental models [1]. This could be partly because leptin has been reported to be pro-inflammatory, albeit in other contexts. However, it is unclear as to why leptin has specific effects at sites of diabetic complications which appear independent of its profound effects on appetite.

Protein modifications and turnover

One of the most complex processes that occur within cells is the folding of proteins, where stoichiometry dictates the final structure aided by posttranslational modifications such as advanced glycation, glycosylation, and phosphorylation. Indeed, changes in the functional properties of proteins are postulated as major contributors to chronic diseases including diabetic complications, which share the pathologic feature of aggregated misfolded protein deposits. This suggests the exciting possibility that "protein-misfolding" may present a common target for therapeutic intervention in diabetic complications [27].

Autophagy

Autophagy is a cellular process that recycles amino acids during times of need, including starvation and metabolic disorders such as diabetes [28]. These amino acids are primarily fed into the mitochondria to produce ATP via oxidative phosphorylation. Therefore, changes in autophagy could facilitate the use of inappropriate fuels for energy production. In diabetic microvascular disease, the study of autophagy is a relatively recent area of research. The growth factor, hepatocyte growth factor (HGF) has been shown to ameliorate diabetic vascular complications, which is thought, at least in part, to be via autophagic clearance of proteins and amino acids irreversibly modified by advanced glycation [1]. With respect to diabetic neuropathy, there is one study which shows that exposure of a neuronal cell line to sera from individuals with T2DM and neuropathy leads to the formation of autophagosomes and the expression of the autophagy-associated protein, beclin-1 [1]. In addition, there is evidence that the serine threonine kinase target of rapamycin (mTOR) can regulate autophagy in renal cells. Furthermore, recent studies have shown that either deletion or upregulation

of components of the mTOR pathway, including the mTOR complexes, mTORC1, and mTOR2 [29,30] contribute to the development of diabetic nephropathy. These studies suggest that changes in autophagy may contribute to structural and functional decline at sites of diabetic complications via disruption of cellular "spring cleaning" of damaged proteins. This exciting area of research warrants further investigation.

Posttranslational modifications of proteins
Enzymatic glycosylation
Glycosylation is a critical enzymatic posttranslational modification resulting in the addition of glycans onto proteins, lipids, and other organic molecules. N-linked glycosylation, which most commonly occurs within the endoplasmic reticulum (ER), is important for the folding of a number of proteins affecting their trafficking and secretion and retention in apical membranes. ER-stress, which occurs as a result of accumulation of misfolded proteins which ultimately may overwhelm protective pathways leading to cellular apoptosis, has been shown as a common pathologic feature of diabetic microvascular complications [31]. In this context, ER stress is thought to be initiated by a number of important pathologic pathways such as advanced glycation and angiotensin II. There is some discordance, however, as to whether oxidative stress specifically is able to initiate ER stress, independently of glucose. Indeed, activation of the ER stress response occurs within the diabetic kidney or in isolated renal cells under high glucose conditions [1]. Furthermore, microarray studies using human renal biopsies from individuals with diabetes have demonstrated higher expression of specific ER stress-associated proteins including BiP (HSPA5), calnexin, and XBP-1.

Some therapies such as intravitreal injection of a purified recombinant adeno-associated virus vector (rAAV2)-58-kilodalton inhibitor of protein kinase (P58(IPK)) protect against diabetic retinopathy via improvements in endoplasmic reticulum stress. Furthermore, inhibition of ER stress ameliorates retinal inflammation in both diabetic- and oxygen-induced retinopathy mouse models. These findings suggest that ER stress is potentially an important mediator of retinal inflammation in diabetes [1].

Advanced glycation
Advanced glycation of free amino groups on proteins and amino acids is a nonenzymatic posttranslational modification first discovered in food chemistry more than 100 years ago by the physician Louise Camille Maillard [32]. This reaction is influenced by many factors and is as heterogeneous as the complex biochemical reactions by which these advanced glycated products can be formed. This involves the formation of Amadori products, glycolysis, TCA cycle, the pentose phosphate pathway, glyceraldehyde-3-phosphate, and generation of the reactive carbonyl methylglyoxal. Physiologically, advanced glycation is postulated as an evolutionary pathway for labeling of senescent cellular amino acids for their recognition and

ultimate turnover but it is likely that this is an over-simplistic view of these complex modifications. Indeed, recent evidence has shown that advanced glycation may modulate insulin secretion [33] and signaling [34,35], although the ultimate influence of this particular action on diabetic complications is yet to be determined. In addition, advanced glycation is thought to stabilize extracellular matrix proteins via cross-linking. It is therefore likely that these posttranslational modifications have other as yet undiscovered physiologic roles. In diabetes, not only do long-lived proteins become more heavily modified but short-lived proteins are also altered by advanced glycation.

The consequences of excessive modification of proteins by advanced glycation are numerous. Extracellular generation of AGEs alters matrix–matrix, cell–cell, or matrix–cell interactions. This has been shown under pathologic conditions to excessively cross-link the matrix resulting in stiffening and slow turnover rates. Intracellular AGE modification of extracellular matrix proteins may also alter their secretory properties and folding. In particular, modification of collagens including type IV collagen, a basement membrane glycoprotein, has been shown to alter cell adhesion thereby changing physiologic protein interactions [1].

Intracellularly, advanced glycation can directly alter trafficking and protein function. Altered production of glycolytic or Kreb's cycle intermediates or reactive oxygen species, would also lead to modification of proteins by advanced glycation [12].

AGE-modified proteins may also interact with cellular receptors. There are many AGE receptors [1], but the most widely scrutinized in diabetic microvascular complications is the receptor for advanced glycation end-products (RAGE). RAGE has many other ligands including HMGB-1, S100 calgranulins and beta-amyloid. Physiologically, the RAGE role is critical for amplification of immune and inflammatory responses, and is highly expressed on mucous membranes. The ligation of AGEs to RAGE also results in ROS generation via NAD(P)H oxidase and mitochondrial pathways. Soluble RAGE (a decoy receptor for RAGE) or RAGE neutralizing antibodies have also shown protection against complications in experimental models, findings which are also seen in RAGE-deficient mice. Conversely, transgenic overexpression of RAGE worsens kidney disease in diabetic mice [1].

Advanced glycation can activate common downstream pathways which contribute to fibrosis via excess accumulation of extracellular matrix proteins, most likely induced via RAGE. Specifically relevant to diabetic complications, AGEs can induced the production of chemokines such as monocyte chemoattractant protein (MCP-1) as well as pro-fibrotic cytokines and growth factors including transforming growth factor-β1 (TGF-β1), connective tissue growth factor (CTGF), and the angiogenic growth factor, vascular endothelial growth factor (VEGF).

Evidence to suggest a pathologic role for advanced glycation in diabetic complications primarily comes from rodent studies, which have clearly shown the efficacy of AGE-lowering

therapies such as pyridoxamine, thiamine, alagebrium chloride, and OPB-9195 as well as lowering AGE dietary intake in averting and retarding experimental diabetic nephropathy [1]. The contribution of dietary AGEs to the development and progression of complications remains controversial.

Manipulation of the enzyme glyoxalase-1, which is responsible for the removal of the AGE precursor methyglyoxal (MGO), also lowers the tissue accumulation of AGEs. Indeed, lowering MGO via manipulation of glyoxalase-1 activity has functional and structural benefits for diabetic neuropathy [36] and retinopathy. Therefore, approaches that increase the activity of glyoxalase-1 or decrease the accumulation of methylglyoxal may also be worth considering as therapeutic targets in diabetic microvascular complications.

Phosphorylation

The key intracellular second messenger, protein kinase C (PKC) is a family of enzymes including at least 11 isoforms, which have been classified into three groups: (i) the conventional group which includes PKC-α, β1, β2, and γ, (ii) the novel group, and (iii) the atypical group. PKC can be activated by glucose as well as other stimuli characteristic of the diabetic milieu such as AGEs and Angiotensin II. The best studied in diabetic microvascular disease is PKC-β [37]. Preclinical studies [37] have also been performed with the relatively selective PKC-β inhibitor, ruboxistaurin which inhibits both the PKC-βI and -βII isoforms. These studies defined that one of the key molecular events in the diabetic kidney that appeared to be PKC-β dependent was renal TGF-β1 expression.

A series of mice with deletions of individual isoforms of PKC have also been studied. Mice with a deletion of PKC-β after induction of diabetes, did not develop renal hypertrophy [37], or upregulation of proteins which compose the extracellular matrix including collagen and fibronectin as a result of reduced expression of the key prosclerotic growth factors TGF-β and CTGF. Oxidative stress is also attenuated in the kidneys of these diabetic mice [37]. Consistent with the major effect of PKC-β being via a TGF-βI dependent pathway, no decrease in urinary albumin excretion was observed, a phenomenon similar to that seen in diabetic rodents treated with a TGF-β1 neutralizing antibody.

In contrast to the PKC-β KO mice, the PKC-α KO mice in response to diabetes have more prominent effects on urinary albumin excretion in addition to a decline in renal VEGF expression, as well as restoration within the glomerulus of the podocyte specific protein, nephrin [37]. This is a highly relevant finding since nephrin is strongly implicated in the pathogenesis of proteinuria including in the diabetic setting with nephrin gene deletion, nephrin gene mutations, and acquired nephrin deficiency as seen in diabetes with all these alterations in nephrin associated with increased proteinuria.

Mitogen-activated protein kinases (MAPK) including p38, initiate an intracellular cascade in response to stimuli such as cytokines, and are thought to be integral mediators of cell differentiation and apoptosis each important for the development of diabetic complications [38]. Indeed, a range of MAP kinases have been examined in the diabetic microvascular setting including p38 MAP kinase. Initially, *in vitro* studies demonstrated that mechanical stretch in mesangial cells leads to p38 MAP kinase activation ultimately resulting in enhanced TGF-β1 and fibronectin expression [38]. Subsequently it was shown that reactive intermediates, such as the AGE intermediate methylglyoxal, which are increased in diabetes could activate p38 MAP kinase. Furthermore, certain effects of AGEs also appear to involve this signaling pathway [1]. With respect to human diabetic nephropathy, there is increasing evidence demonstrating enhanced expression of phospho ERK and p38 MAP kinase in a range of renal cell populations including mesangial cells, podocytes, endothelial cells, proximal tubular cells, and mononuclear cells within the interstitium. p38 Inhibitors have been administered to diabetic rats where effects on intrarenal hemodynamics and blood pressure were demonstrated. In addition, the p38 inhibitor, SB203850, attenuates glucose-induced tubular cell apoptosis [39]. It remains to be determined, however, if targeting p38 MAPK has benefits on the long-term renal functional and structural manifestations of diabetic nephropathy.

In the diabetic retina glucose-mediated effects on retinal pigmented epithelial cells are mediated by p38 MAPK and ERK. In addition, in models of experimental diabetes, inhibition of p38 MAPK improves retinopathy and sensory nerve function [40]. Furthermore, diabetic mice with a deficiency in MKK3, which is an upstream kinase of p38 MAPK, do not develop microvascular disease.

c-Jun N-terminal kinases (JNKs) also belong to the mitogen-activated protein kinase family and as such are responsive to stress stimuli, facilitate apoptosis and T-cell differentiation. JNK signaling has been reported as being elevated in both human and experimental diabetic complications, in particular nephropathy. In experimental models, however, inhibitors of JNK or mice with genetic deficiencies in JNK1 or JNK2 [41,42] exacerbate urinary albumin excretion and worsen the integrity of the glomerular filtration barrier in the diabetic kidney. These data contrast with other models of progressive renal disease. In a model of nondiabetic retinopathy, retinopathy of prematurity, retinal neovascularization is also improved with JNK inhibition [43]. However, the role of JNK in the development of diabetic retinopathy remains to be elucidated.

Oxidative imbalances

Nicotinamide adenine dinucleotide phosphate (NAD(P)H) oxidase

NAD(P)H oxidase [44] was originally thought to only function in neutrophils to generate vast quantities of superoxide (O_2^-) by electron transport to destroy microbes and infected cells.

Generally, it is composed of membranous and cytosolic components and a GTPase, *rac*1 or *rac*2. Within the membrane, p22phox and Gp91phox are the major isoforms identified. Gp91phox has a number of tissue specific homologues which include Nox-5 (humans only), Nox-1, and Nox-3. The cytosolic specific subunits are p47phox, p67phox, as well as p40phox (PMID: 23379642).

Within the kidney, particular subunits are thought to be important for function. These include Nox-4, originally identified in renal tissues, which is a unique subunit in that it does not require the other subunits to generate O_2^-. Although originally discovered in the cytosol, Nox-4 has been recently discovered in the mitochondria.

In contrast to what was initially thought, nonphagocytic cells also express NAD(P)H oxidase [45], but the capability for production of O_2^- is significantly less than in immune cells such as neutrophils. This is likely due to their differential physiologic roles, where white blood cells use NAD(P)H oxidase as a killing mechanism while in nonphagocytic cells the ROS generated are postulated to act as second messengers. Cytokines and hormones such as angiotensin II and AGEs when they ligate to their receptors rapidly activate NAD(P)H oxidase. In diabetic mice deletions of the specific NAD(P)H oxidase subunits or treatment with antisense oligonucleotides lead to improved end-organ function [44]. Although NAD(P)H oxidase may contribute to the pool of excess ROS, there are some major challenges to be overcome when targeting this pathway including redundancy among Nox isoforms and preservation of intracellular O_2^- generation for use as either second messengers or alternatively in host-pathogen defense.

Nitric oxide synthase

Nitric oxide is produced frequently as a cellular signaling molecule by numerous cell populations. The enzyme responsible for its production from NADPH, L-arginine and oxygen often in the presence of cofactors such as bihydrobiopterin (BH_4) and flavin adenine dinucleotide (FAD), is nitric oxide synthase (NOS), which has multiple isoforms, inducible (iNOS), neuronal (nNOS), and endothelial (eNOS). In addition to cell signaling, NO is a powerful vasodilator and is generally thought to be vasoprotective in the context of diabetes [46].

In diabetes, there is previous evidence that uncoupling of NOS due to restriction of L-arginine availability is a major source of superoxide at sites of diabetic complications, which is produced in preference to NO in that context. There is, however, some controversy as to the contribution of NOS uncoupling to diabetic complications. This is due to the temporal changes seen with NO over the course of diabetic complications. For example, early in disease development, NO production within tissues is thought to increase as a result of changes in NOS activity and therefore it has been postulated that therapeutic blockade of this pathway could be beneficial at this time. Indeed, a deficiency in iNOS or pharmacologic inhibition of NOS improves nerve conduction velocity in animal models of diabetic neuropathy [1].

Later in the disease, it is thought that functional decline in complication-prone organs is seen in conjunction with a state of progressive NO deficiency. These deficiencies in NO production could be the result of many pathways, including glucose and AGE quenching and inhibition and/or posttranslational modification of NOS. In support of this, several studies show that chronic NO inhibition has no effects or detrimental outcomes for renal disease as a consequence of diabetes [1]. This is also the case for blockade of nNOS in experimental diabetic neuropathy, where nNOS-deficient mice are not protected against diabetes-induced loss of sensory perception and intra-epidermal nerve fiber loss.

Mitochondrial sources

The excess generation of superoxide (O_2^-) by dysfunctional mitochondria has been postulated as an early event in diabetic complications [47]. This is because within mitochondria, more than 90% of oxygen in humans is metabolized during oxidative phosphorylation which utilizes glucose metabolites and other fuels that donate electrons to reduce molecular oxygen, resulting in ATP generation. Under physiologic conditions, about 1% of oxygen is only partially reduced to O_2^-, instead of fully to water. There are two major sites where electron leakage can occur to produce superoxide within the mitochondria, at NADH dehydrogenase (Complex I) and at the interface between Coenzyme Q (CoQ) and complex III. Therefore, based on *in vitro* studies, it has been hypothesized that excess production of O_2^- is via the premature collapse of the mitochondrial membrane potential so that electrons leak to form O_2^- and then H_2O_2 occurs rather than ATP production. However, there has never been substantiation of this phenomenon in *in vivo* models of diabetes. Despite this, there are a number of studies demonstrating mitochondrial functional abnormalities at sites of diabetic complications [12].

This is part of the therapeutic rationale for the use of antioxidants which may target the mitochondrial production of superoxide to treat diabetic complications. Idebenone is an antioxidant with preferential mitochondrial uptake by organs such as neurons, kidney, and cardiac tissues. This compound is clinically used in human respiratory chain diseases such as Friedreich Ataxia where mitochondrial generation of ATP appears to be preserved [48], particularly in cardiac tissues. Administration of exogenous Coenzyme Q has shown therapeutic benefits in animal models of diabetic complications [49,50]. A third agent, Mito Q, under investigation for the treatment of Alzheimer's disease in humans, is selectively taken into mitochondria as the result of a lipophilic triphenylphosphonium cation (www.antipodeanpharma.com). There have been studies determining the therapeutic potential of MitoQ to decrease vascular complications in experimental models of T1DM [51] and this is an area of research warranting further attention.

Antioxidants

Humans and rodents have a number of antioxidant systems that specifically control tissue ROS concentrations. Superoxide dismutase is the first of these, catalyzing the conversion of superoxide to hydrogen peroxide, consisting of three major isoforms, copper zinc superoxide dismutase (CuZnSOD, SOD1), manganese SOD (MnSOD, SOD2), and extracellular SOD (SOD3). Hydrogen peroxide is then converted to water by antioxidants such as glutathione peroxidase (GPx) and catalase. There are numerous other important cellular antioxidants, such as glutathione and numerous vitamins [12].

It is well appreciated that there are changes in the expression and activity of antioxidant enzymes at sites of diabetic microvascular disease [12]. Mice with genetic manipulations of various antioxidant enzymes such as GPx-1, however, do not develop microvascular disease despite having increased tissue hydrogen peroxide concentrations, although they do appear to be more susceptible to atherosclerosis. This is most likely due to redundancy with other GPx isoforms. Catalase overexpression is, however, protective in experimental models of type 2 diabetic nephropathy. Modulating antioxidant activity as a potential therapy for diabetic complications remains disappointing in clinical trials, however, despite some benefits of agents such as α-lipoic acid on pain and muscle weakness in diabetic polyneuropathy [1].

Inflammation

An intact acute inflammatory cascade is critical for innate immunity, and is triggered in response to a real or perceived threat to tissue homeostasis. Although the innate immune response is relatively nonspecific, adaptive immunity allows the human body to recognize and remember pathogens resulting in the capacity for an enhanced inflammatory response upon subsequent exposure to the same pathogen. Acute inflammation is a tightly regulated cascade of factors such as pro-inflammatory cytokines (e.g. tumor necrosis factor TNF-α and interleukins), chemokines (Chemokine C-C motif ligand-2 and 5; CCL2 and CCL5 and fractalkine CX3CL1), and adhesion molecules (e.g. E-selectin; intercellular adhesion molecule, ICAM-1 and vascular cell adhesion molecule, VCAM-1), that initiate the interaction between leukocytes and the endothelium to facilitate leukocyte migration towards infected or injured tissue. While acute inflammation as part of innate and adaptive immunity is beneficial, excessive or uncontrolled inflammation can promote tissue injury. Chronic inflammation is postulated as a characteristic feature seen at sites of diabetic complications.

Adhesion molecules

Hyperglycemia, hypertension, and dyslipidemia each contribute to activation of the endothelium leading to inflammation via a number of pathways including oxidative stress, NF-κB activation, dysregulation of nitric oxide synthase (NOS), and formation of advanced glycation end-products (AGEs). Not surprisingly, activation of the endothelium is a common manifestation seen in diabetes [52] where ICAM-1, VCAM-1, and E-selectins are expressed recruiting leukocytes to sites of diabetic complications. In the diabetic context, deletion of ICAM-1 protects against the development of renal disease in both experimental type 1 [53] and type 2 mouse models [54], which is also seen for retinopathy where blockade of ICAM-1 is protective against blood–retinal barrier breakdown, capillary occlusion, and endothelial cell damage [55,56].

Soluble isoforms of VCAM-1 and ICAM-1 can also be liberated by activated endothelial cells resulting in activation of leukocytes and their chemotaxis to damaged tissue sites. Increased circulating levels of sVCAM-, sICAM-1, and E-selectin are closely associated with both their increased surface expression on endothelial cells and with diabetic renal, retinal, and macrovascular complications in humans. There is also some evidence linking the levels of sVCAM-1and sICAM-1 to diabetic neuropathy [1].

Inflammatory cell infiltration

Phagocytic cells such as monocytes and macrophages are often the first infiltrating cells that arrive at sites of diabetic complications [57,58] in response to chemotactic molecules. A number of rodent studies have suggested a causal role for monocytes and macrophages in the development of diabetic complications [59]. In addition, blockade of the production of chemotactic molecules such as CCL2 is also beneficial in preventing diabetic complications in rodent models. In models of experimental diabetes, a deficiency in CCL2 impedes renal monocyte and macrophage accumulation and improves diabetic renal injury. Of course, these effects need to be considered in the context of a putative metabolic effect of CCL2 in addition to other inflammatory molecules on insulin sensitivity.

In experimental diabetes, changes in the signaling of CCL-2 which alters the actin cytoskeleton, affects nephrin expression in glomerular podocytes contributing to albuminuria. These changes in cytoskeletal rearrangement are also likely to be important for other cell types affected by diabetes. Furthermore, administration of pharmacologic antagonists of the CCL-2 receptor, CCR-2, in experimental models of diabetic nephropathy, reduced renal hypertrophy and macrophage infiltration within renal glomeruli [60,61].

Upon arrival and activation within damaged tissues, monocytes and macrophages facilitate the chemotaxis of other leukocytes such as T cells via secretion of a number of factors including interleukin -1β (IL-1β) and CCL5. Although experimental studies have shown that depletion of T-cell populations at sites of vascular injury is beneficial for atherosclerosis, other studies have shown that depletion of both β- and T-cell populations using diabetic Rag1 KO mice does not influence the development and progression of diabetic nephropathy [62]. Therefore, it seems that this area of research requires further clarification.

Inflammatory cytokines

Cytokines are complex interactive molecules affected by factors such as cell type, timing, and the context of their expression. These molecules are able to share receptors and act synergistically to amplify their effects and therefore it is likely that they may be difficult to rationally target therapeutically. Interleukin-1 is a cytokine released by immune cells, resident monocytes, macrophages, adipocytes, and other cells at sites of diabetic complications. The primary role of this cytokine is the recruitment and activation of other leukocytes by enhancing the expression of adhesion molecules. Indeed, there is some evidence that inhibition of IL-1β may represent a safer alternative than the more commonly targeted growth factor, vascular endothelial growth factor, in retinal degeneration [1]. The release of IL-1β also has a number of other effects on cells, including secretion of prostaglandins which alter local hemodynamics. In diabetic neuropathy, IL-1β has been interrogated more closely where it has been shown to induce nerve damage and miscommunication between Schwann cells and axons [1].

Interleukin-6 is a cytokine which can mediate cell proliferation, endothelial cell permeability and matrix overproduction. Both IL-6 and tissue necrosis factor (TNF)-α have been shown to influence glial cell and neuron behavior, these findings relevant to both diabetic neuropathy and retinopathy in humans. TNF-α signaling has also been targeted using the pharmacologic agent pentoxifylline to improve kidney function [63]. Given that TNF-α has a major role in the regulation of immune cell function, therapies targeting this axis would need to be extensively tested including detailed assessment of safety.

Nuclear transcription factor Kappa B (NF-κB)

NF-κB is a dimeric transcription factor commonly composed of p50 and p65 subunits [64], which is sequestered in the cytosol by the inhibitor of NF-κB, I-κBα. Following phosphorylation of I-κBα by IκB kinase β (IKKβ), NF-κB dimers undergo nuclear translocation. The p65 subunit is thought to be a transcriptional activator controlling genes such as angiotensinogen, cytokines, and adhesion molecules in the diabetic environment [64,65]. Nuclear translocation of NF-κB is also facilitated by hyperglycemia, excess ROS, iNOS activation, and AGEs [1]. We have demonstrated that NF-κB plays a role in early renal macrophage recruitment and infiltration in the diabetic kidney [66,67]. It is thought that in diabetic vascular complications, NF-κB is a central node which may control hemodynamic and glucose-dependent signaling pathways.

The compound Bardoxolone methyl, has demonstrated potential benefits on chronic kidney disease primarily via improvements in estimated GFR (as discussed in Chapter 41). It is thought that Bardoxolone activates the Kelch-like ECH-associated protein 1(KEAP-1)-Nrf-2 pathway, where KEAP-1 regulates NF-κB by controlling the ubiquination and breakdown of IKKβ. This is supported by research which shows that depletion of KEAP1 results in the accumulation and stabilization of IKKβ with subsequent upregulation of NF-κB-derived factors. KEAP-1-Nrf-2 pathways have also been shown to regulate ROS production in cardiac cells which may also be relevant to other sites of diabetes complications where changes in NF-κB are seen. However, recent preclinical studies suggesting nephrotoxicity [68] as well as the recent premature termination of a major clinical trial with this agent (http://www.reatapharma.com/investors-media/news/news-timeline/2012/company-statement-termination-of-beacon-trial.aspx) has reduced enthusiasm for this drug as a renoprotective agent.

Pyrrolidine dithiocarbamate (PDTC) is an experimental NF-κB inhibitor which has been used in both diabetic [66] and nondiabetic animal models where it has shown benefits on renal function, but this drug's toxicity profile has inhibited its direct translation to the clinical setting. It is appreciated, however, that a number of therapeutics affect the nuclear translocation of NF-κB, including metformin, aspirin, vitamin B derivatives, carnosine, and thiazolidinediones [1]. However, approaches to inhibit NF-κB have not been explored fully in diabetes in humans, most likely as a result of the intimate involvement of this transcription factor in a number of essential cellular processes including apoptosis and host-pathogen defense.

Conclusion

As is highlighted within this chapter, the complexity of pathways involved in the pathogenesis of diabetic microvascular complications is immense. There is no doubt that diligent control of glycemia and blood pressure has had a positive impact on the morbidity and mortality associated with diabetes in most developed nations. However, given the rise in the number of cases of diabetes, in particular from developing nations, the worldwide rates of diabetic microvascular complications are set to rise dramatically. Hence it is critical to delineate the mechanisms that lead to disease development and progression and how these occur over time. Furthermore, we need to understand the complex relationship between glucose handling by sites such as the liver and pancreatic islets and how this impacts upon the pathogenesis of microvascular complications. This requires the use of rodent and other animal models where we can understand the complex relationships between pathways. The most important step, however, is to apply these findings to the clinical development of disease to discern their importance in this context given that some factors may not translate directly across to human biology. We must also not forget to look to other diseases for a greater understanding of the complex machinery that makes the human body function and how this goes wrong to produce diabetic microvascular disease.

Key points

- Diabetic retinopathy affects one third of persons with diabetes and is the most common cause of reversible visual loss in working adults.

- About 10% of persons with diabetes will have vision-threatening retinopathy, including diabetic macular edema.

- The presence of diabetic retinopathy is associated with an increased risk of other diabetic complications such as nephropathy and cardiovascular diseases.

- Chronic exposure to hyperglycemia and other causal factors (e.g. hypertension) is believed to initiate a cascade of biochemical and physiologic changes that ultimately lead to microvascular damage and retinal dysfunction.

- Optimal management of the modifiable risk factors blood glucose, blood pressure, and blood lipids is key to preventing development and progression of retinopathy.

- Regular dilated eye examinations are effective in detecting and treating asymptomatic vision-threatening diabetic retinopathy. Persons with T1DM should have a complete dilated retinal examination within 5 years from the onset of diabetes. Persons with T2DM should have a complete dilated retinal examination at the time of diagnosis, Subsequent examination and referral for treatment should be determined by the presence and severity of retinopathy.

- Laser photocoagulation can prevent visual loss in proliferative retinopathy and diabetic macular edema. Intraocular administration of vascular endothelial growth factor inhibitors have been established as useful new treatment modalities in diabetic macular edema. Surgical intervention by vitrectomy may occasionally be indicated in advanced proliferative disease.

Introduction

Diabetic retinopathy (DR) is a clinically well-defined, specific microvascular complication of diabetes, which is likely to develop to some degree in nearly all patients with diabetes mellitus over time. Although diabetes affects the eye in multiple ways (e.g. increases the risk of cataract and retinal vascular occlusions) [1], DR is the most common and specific ocular complication, being the leading cause of visual loss in working-aged adults in the developed world [2]. Of the 366 million persons with diabetes worldwide [3], one third will have diabetic retinopathy, of which a third is likely to have vision-threatening retinopathy, which includes severe or proliferative retinopathy and diabetic macular edema [4]. Diabetic retinopathy is reported to cause visual impairment in 10–20% of persons with diabetes [4–9]. Although DR blindness appears to have fallen in the developed world [6–8], the rapidly increasing number of persons with diabetes worldwide, especially in developing countries [10–12] where access to optimal medical care may be limited, has led to a continuing increase in the global burden of this disease [11,13–15].

Diabetic retinopathy is characterized by changes and lesions in the retinal vasculature including hemorrhages, microaneurysms, arteriolar and venular dilatation. These have a progressive nature eventually leading to areas of retinal nonperfusion, increased vasopermeability with retinal edema and exudates, and pathologic proliferative of intraocular blood vessels resulting in hemorrhage, tractional retinal detachment or neovascular glaucoma, all of which contribute to visual impairment and blindness. Apart from its effects on vision, the presence of DR also signifies a greater risk of life-threatening systemic vascular complications [16].

Recent epidemiologic, genetic, and experimental studies have furthered our understanding of the pathophysiology underlying DR. In addition, over the last 5 years, there have been several large-phase clinical trials that have provided contemporary data regarding evidence-based treatment strategies for DR, including systemic management and ocular treatment using

antivascular endothelial growth factor (VEGF) agents. These have provided paradigm shifts in management of DR and diabetic macular edema.

Prevalence of diabetic retinopathy

The epidemiology of DR is well described in the literature. In many countries, DR is the most frequent cause of preventable blindness in working-aged adults [17]. In a major meta-analysis, Yau et al. described the global prevalence of DR based on 35 studies across the world with a total of 22,896 patients with diabetes and estimated the prevalence of any retinopathy to be 34.6% with 10.2% having vision-threatening retinopathy [4].

In the United States, a pooled analysis of data from different studies reported a prevalence rate of 40% for any retinopathy and 8% for vision-threatening retinopathy in T2DMs and 86% (42% for vision-threatening retinopathy) in T1DM [18,19].

Similarly high prevalence estimates have been reported in other countries (Figure 61.1) [20]. Amongst white Caucasian populations, there have been studies in the UK, Europe, and Australia [21–25]. Data from western Scotland showed the prevalence of any DR to be 26.7% [26]. Studies from Danish populations have shown an overall prevalence of retinopathy of 77% in men and 74% in women with T1DM [27]. Variations in the prevalence of retinopathy may be due in part to differences in population selection and in methods for assessing retinopathy.

In Australia, three large population-based studies assessed DR from a standardized grading of fundus photographs. The Melbourne Visual Impairment Project reported a retinopathy prevalence of 29.1% among persons aged 40 years or older with self-reported diabetes [28]. The Blue Mountains Eye Study found a similar retinopathy prevalence of 32.4% among older persons aged 49 years and above with known or newly diagnosed diabetes [29], with signs of proliferative disease in 1.6% and macular edema in 5.5%. The Australian Diabetes Obesity and Lifestyle (AusDiab) study examined 11,247 adults aged 25 years or older from 42 randomly selected urban and rural communities [30]. Overall, 25% of participants with known diabetes were found to have retinopathy, including 2% with proliferative retinopathy. As in other studies, the prevalence of retinopathy was strongly related to the duration of diabetes, with a prevalence of 9.2% among those with a duration of less than 5 years, 23% for durations between 5 and 9 years, 33% for durations between 10 and 19 years, and 57% for those with a duration of 20 or more years.

In many Asian countries, the prevalence of diabetes has increased substantially over the past few decades [15,31–34], and there is concern about a potential diabetes epidemic in Asia [35]. In Singapore, for example, serial population surveys in 1975, 1985, and 1992 showed increasing prevalence rates of diabetes of 2%, 4.7%, and 8.6%, respectively, in the population between the ages of 15 and 69 years [33,34]. There are now increasing data on the epidemiology of diabetic retinopathy
Figure 61.1 Prevalence of diabetic retinopathy in various studies.

in Asians [36–38]. In China, the Beijing Eye Study and the Handan Eye Study examined the prevalence of DR in urban and rural Chinese persons, respectively [36,38,39]. In the Beijing Eye Study, the prevalence of DR detected on the fundus photographs was 37.1%, with macular edema present in 5.2%, clinically significant macular edema in 2.6%, and vision-threatening retinopathy in 5.2%. Diabetic retinopathy was associated with rural region, longer duration of diabetes, diabetic medications use, and lower education status. The Handan eye study in a rural region in China shows that diabetic retinopathy is common, with prevalence rates of 43% for any retinopathy, 5.2% for macular edema, and 6.3% for vision-threatening retinopathy [36]. Like in other studies, the prevalence of retinopathy was strongly related to duration of disease. These estimates are higher than those reported in another study in Beijing amongst mostly urban Chinese residents [39], suggesting the need to target preventative efforts in rural areas of China. Based on these data, there are an estimated 9.2 million Chinese persons living in rural areas with DR, of whom 1.2 million have vision-threatening retinopathy [36]. There is thus a pressing need for appropriate screening and management of diabetes and its complications in rural China.

The Singapore Malay Eye Study [37] reported on DR in Asian Malays, the third largest ethnic group in Asia. The overall prevalence of any retinopathy was 35.0%, macular edema 5.7%, and vision-threatening retinopathy 9.0%. Independent risk factors for any retinopathy were longer diabetes duration, higher hemoglobin A1c, hypertension, and higher pulse pressure. Vision-threatening retinopathy additionally was associated with previous stroke, cardiovascular disease, and chronic kidney disease.

In Indians, the Aravind Eye Disease Survey in southern India reported a retinopathy prevalence of 27% in a population aged 50 years or older with self-reported diabetes [40], similar to the 22% prevalence reported from another population-based study in an urban population in Hyderabad, India [41]. The Singapore Indian Eye Study examining an urban population of ethnic Indians aged 40 and older, found a prevalence of 30.4% for any retinopathy, 7.2% for macular edema, and 7.1% for vision-threatening retinopathy. The independent risk factors for any retinopathy were younger age, longer diabetes duration, higher hemoglobin A1c, higher systolic blood pressure, lower diastolic blood pressure, previous stroke, and insulin treatment [42]. Thus, these population data suggest that diabetic retinopathy is common in Asian populations with diabetes, who share similar risk factors to White populations, suggesting that control of these risk factors may reduce both the prevalence and impact of retinopathy.

Incidence and progression of diabetic retinopathy

There are fewer data on the incidence and natural history of diabetic retinopathy. In the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR), the 4-year incidence of retinopathy was 40% [43,44], the 10-year incidence of retinopathy was 60–70% [45], and the 10-year incidence of macular edema was 15–25% [46]. There are few other long-term population-based incidence data using objective measures to detect retinopathy to compare with these findings [47–54]. In the United Kingdom Prospective Diabetes Study (UKPDS), a multicenter randomized clinical trial, the 6-year incidence of retinopathy was 41% [53]. The Liverpool Diabetic Eye Study reported an annual incidence of sight-threatening retinopathy of 0.3% in the first year, rising to 1.8% in the fifth year [54].

Time trends in the epidemiology of diabetic retinopathy

There have been some suggestions that over the past 30 years, better recognition and management of retinopathy risk factors and the institution of structured retinopathy screening programs have led to a decline in both the prevalence and incidence of moderate to severe microvascular diabetic complications.

Studies conducted in contemporary populations have suggested this to be the case. For example, data from both the UKPDS [53] and the Liverpool Diabetic Eye Study [54] show lower incidence rates for retinopathy, particularly sight-threatening retinopathy, than was reported previously in the WESDR and studies in the early 1980s [55]. A recent study assessed the age at which retinopathy was first diagnosed in a sample of patients with T1DM and showed that the median diabetes duration until the first occurrence of retinopathy was 16.6 years [56], which is longer than reported in previous studies. The meta-analysis review showed that estimates of retinopathy prevalence were about 10–20% lower in the seven later studies as compared to the initial WESDR prevalence [18]. The WESDR follow-up study showed that from 1980 to 2007, the estimated annual incidence of proliferative DR decreased by 77% and vision impairment decreased by 57% among persons with T1DM [6].

These data suggest that improvements in diabetes management and improved levels of metabolic and blood pressure control may have had a positive impact in reducing the prevalence and incidence of retinopathy in Western countries. Nevertheless, it is uncertain whether this declining trend will continue, with expectedly increasing number, duration, and lifespan of people with diabetes [57]. These trends however, may not apply to Asian populations. In the Handan Eye Study [36], the prevalence of retinopathy was 43.1%, higher than those reported in contemporary studies in Whites (ranging from 15.3% to 29.0%), Blacks (27.7–36.7%), and in Asian Indians (17.6%). In fact, the Handan Eye Study suggests that the prevalence of retinopathy in rural Chinese populations is more similar to rates seen in the initial WESDR.

Table 61.1 Risk factors for diabetic retinopathy

Modifiable risk factors	Non-modifiable risk factors
Hyperglycemia	Age
Hypertension	Diabetes duration
Dyslipidemia	Ethnicity (Hispanic, South Asian)
Cataract surgery	Genetic predisposition
Obesity*	Puberty
Smoking*	Pregnancy
Alcohol consumption*	Nephropathy

*Risk factors with inconsistent evidence.

Risk factors

There are several important risk factors for diabetic retinopathy (Table 61.1).

Hyperglycemia, hypertension, and dyslipidemia

The three major modifiable risk factors, including hyperglycemia, hypertension, and dyslipidemia are discussed in greater detail in the section on systemic management of diabetic retinopathy. Briefly, reducing glycated hemoglobin levels by 1% through intensive glycemic control reduced the risk of DR by 15–40% [58], progression to vision-threatening retinopathy by 25% [59], need for laser photocoagulation by 25–30%, and risk of legal blindness by 16% [60]. Controlling hypertension with a 10 mmHg decrease in systolic blood pressure reduces the risk of DR progression by 34%, visual loss by 37%, and need for laser photocoagulation by 35% [61]. Epidemiologic studies have not found a consistent association between serum lipid levels and DR. However, studies have found that fibrates may be protective against DR progression [62,63].

Duration of diabetes

Epidemiologic studies have shown that the prevalence of diabetic retinopathy in persons with diabetes increases with the duration of disease. The WESDR study reported that after 20 years of diabetes, nearly 99% of T1DM patients and 60% of T2DM patients had developed DR [64,65]. Age of onset also plays an important role as DR rarely develops in children under 10 years of age irrespective of duration of disease.

Race

Racial/ethnic differences in the prevalence of diabetic retinopathy have been a major focus of recent research. Population-based studies suggest that the prevalence and severity of DR are higher in African Americans, Hispanics, and South Asians than in Whites, which is not fully explained by differences in the distribution of retinopathy risk factors [20,66–68]. For example, the UK Asian Diabetes Study showed that after controlling for retinopathy risk factors, South Asians were more likely to have diabetic retinopathy than Whites [20], a finding also supported by a recent large clinical trial [69]. Nevertheless, it is uncertain whether these apparent ethnic variations represent subpopulation differences associated with medical care, or variability in genetic predisposition to microvascular damage.

Genetic factors

There is evidence to support a genetic component for diabetic retinopathy [70,71]. Familial aggregation studies and clinical trials including the Diabetes Control and Complications Trial (DCCT) have demonstrated a heritable tendency for DR independent of shared risk factors [72]. Studies of other populations reported similar heritability for severe DR not fully explained by lifestyle or environmental factors [70]. A recent meta-analysis identified several genes (e.g. aldose reductase gene) associated with DR [71].

Gender

In women, pregnancy and puberty are risk factors for diabetic retinopathy in T1DM [73–75]. In the WESDR, diabetes duration after menarche, a marker of puberty onset, was associated with a 30% excess risk of retinopathy compared to diabetes duration before menarche [73]. Pregnancy is similarly associated with progression of diabetic retinopathy and risk of vision-threatening retinopathy both in T1 and T2DM [76–78]. Planned dilated retinal examination should be offered for patients with T1DM after puberty and for all pregnant women with pre-existing diabetes.

Cataract surgery

In patients with diabetes, cataract surgery has been reported to exacerbate the development and progression of diabetic retinopathy. Macular edema after cataract surgery is also a major cause of vision loss in diabetic patients, especially in those with pre-existing DR. Considerations for the management of the diabetic subjects with a cataract are discussed in the section on ocular management of retinopathy.

Relationship with other complications

Previous epidemiologic studies have also shown that diabetic retinopathy is associated with many other systemic and lifestyle factors, including nephropathy [79], obesity [80], alcohol consumption [81], smoking [82], as well as hematological markers of anemia [83], inflammation, and endothelial dysfunction [84,85]. However, some of these findings have been inconsistent, and the precise role of such factors in the pathogenesis of DR is not well defined.

Diabetic retinopathy reflects widespread end-organ microcirculatory damage and findings from epidemiologic studies suggest that DR predicts an excess risk of systemic vascular complications [16]. The presence of retinopathy, even in its mildest form, may double or triple the risk of coronary heart disease, heart failure and stroke, independent of other vascular

risk factors [86–88]. These findings suggest the need for closer cardiovascular monitoring and follow-up for patients with DR [16].

Pathogenesis

Chronic exposure to hyperglycemia and other risk factors (e.g. hypertension) is believed to trigger a cascade of biochemical and physiologic changes that results in the microvascular damage and retinal dysfunction manifest in diabetic retinopathy (see Chapter 68).

Biochemical changes

Hyperglycemia is considered the key initiator of the cascade of retinal changes associated with diabetic retinopathy. Several biochemical mechanisms are thought to be associated with the pathogenesis of retinopathy through effects on cellular metabolism, signaling, and growth factors [17,89]. Implicated pathways include the accumulation of sorbitol and advanced glycation end-products, oxidative stress, protein kinase C activation, inflammation, and upregulation of the renin-angiotensin system and vascular endothelial growth factor (VEGF). Recognition of the potential roles for each of these processes has led to the development of new therapeutic agents, several of which have been or are currently being tested in clinical trials.

Protein kinase C is a key mediator in intracellular signal transduction and is involved in diabetic microvascular complications [90]. Hyperglycemia increases activation of retinal cellular protein kinase C, leading to increased expression of matrix proteins and vasoactive mediators, with adverse structural (pericyte apoptosis [91], basement membrane thickening) and functional (increased retinal vascular permeability and retinal blood flow) retinal vascular changes.

Hyperglycemia increases glucose flux through the polyol pathway, via which aldose reductase converts glucose into intracellular sorbitol, which may induce osmotic damage to retinal endothelial cells and pericytes. Aldose reductase gene had the largest number of polymorphisms associated with DR [92].

Oxidative stress is also a key process where hyperglycemia increases production of reactive-oxygen species, leading to activation of protein kinase C, formation of advanced glycation end-products, activation of the polyol pathway and VEGF production.

Prolonged exposure to hyperglycemia induces nonenzymatic glycation of proteins to form advanced glycation end-products (AGEs), which may contribute to retinal perictye loss, microaneurysm formation, and vascular endothelial damage. AGEs mediate their effects on the microvasculature through interaction with the receptors for AGEs (RAGE). Modulation of RAGE may be a possible future means of therapeutic intervention for DR [93].

The intraocular renin-angiotensin system has been found to be upregulated in diabetes, and angiotensin II may stimulate expression of VEGF and other growth factors in retinal vascular endothelial cells and promote cell growth, proliferation, and the deposition of extracellular matrix proteins.

VEGF is a key mediator in the retinal vasculature changes involved in the development and progression of DR [94]. Increased levels of VEGF have been shown in the ocular fluids of diabetic patients [95]. In response to hypoxia, retinal endothelial cells, pericytes and pigment epithelial cells express VEGF, stimulating angiogenesis which results in neovascularization and increasing capillary permeability resulting in macula edema.

Recent work has identified new VEGF-independent pathways for DR [96,97]. Among these, erythropoietin has been shown to be a potent ischemia-induced angiogenic factor in proliferative retinopathy which acts independently of VEGF [98,99]. Inhibition of erythropoietin is remarkably effective in suppressing retinal neovascularization in animal models [98,100]. In the retina, erythropoietin is also expressed in response to stimuli other than ischemia [101], and it has been suggested that it may serve to protect the neural retina at the early stage of DR [102,103]. Therapeutic inhibition of erythropoietin as a treatment approach for DR must be balanced by its potential adverse effects on photoreceptor survival [96].

Proteomic analyses have identified other VEGF-independent pathways in DR. The vitreous level of extracellular carbonic anhydrase was markedly elevated in eyes with DR [104]. Inhibiting carbonic anhydrase activity has been demonstrated to reduce retinal vascular permeability in animal models [104]. However, it remains undetermined whether topical carbonic anhydrase inhibitors, which are commonly used to lower intraocular pressure in patients with glaucoma, could reduce the risk of DR [105].

Inflammation has been shown to play a critical role in the pathogenesis of DR [106–108]. An array of inflammatory mediators are upregulated in diabetes in response to hyperglycemia and other stresses (e.g. dyslipidemia) which trigger pro-inflammatory responses that may cause abnormal leukocyte–endothelial interactions and retinal microvascular damage. There is little evidence for a strong association between markers of systemic inflammation and risk of DR suggesting that this it is likely to be a local phenomenon [85,109].

Finally, there are new insights into retinal physiology that suggest the concept that DR cannot be attributed as purely a manifestation of microvascular damage. Neuroretinal compromise may occur early in the course of DR, and can precede the onset of microvascular changes [106]. It has been proposed that diabetes may reduce insulin receptor signaling in the retina, leading to neurodegeneration [106]. Experimental studies suggest that diabetes adversely affects the entire neurosensory retina, with accelerated neuronal apoptosis, and activation or altered metabolism of neuroretinal supporting cells [106]. These findings suggest that DR could be similar to peripheral diabetic neuropathy, but involving the retinal parenchyma. While the

complex relationship between the neural and vascular elements of retinopathy pathogenesis remains to be elucidated [106], understanding how diabetes affects the neural retina may ultimately lead to the development of neuroprotective agents as new potential disease modifiers [110].

Retinal vascular changes

Diabetes and diabetic retinopathy is associated with structural and functional changes in the retinal vasculature [111]. Quantitative assessment of the retinal vasculature with computer-based retinal image analysis has been used to study these changes in greater detail.

Increased retinal arteriolar caliber is found to be associated with the development of retinopathy in both T1 and T2DM [112–114]. Dilation of retinal arterioles may be an early indicator of microvascular dysfunction [115], implying impaired arteriolar autoregulation [114,115]. Based on the laws of Starling and Laplace, retinal arteriolar dilatation has been postulated to increase retinal capillary pressure, leading to capillary wall dilatation (microaneurysms), leakage (edema and hard exudates), and rupture (hemorrhages) [114]. Increased retinal venular caliber is independently associated with the progression of DR [116–120], and predicts the risk of proliferative retinopathy [116]. Proposed mechanisms underlying this association are likely to be multifactorial (e.g. retinal hypoxia, inflammation, endothelial dysfunction) [121–124]. Collectively, these findings suggest that retinal arteriolar dilatation may be an early subclinical marker of microvascular dysfunction preceding the development of nonproliferative DR, whereas retinal venular dilatation may be a marker of progression to more severe or proliferative retinopathy.

Fractal analysis has been used to evaluate the overall geometry of the retinal vascular network in diabetes [125]. A recent study showed that retinal fractal dimension, a measure of the density of the vascular branching pattern, is associated with early retinopathy in T1DM [126]. Furthermore, research investigating new dynamic retinal vascular changes has demonstrated that eyes with DR have reduced retinal vasodilation after flicker-light stimulation, a measure of endothelial dysfunction [127,128]. These imaging techniques may offer new means of assessing DR risk.

Clinical features and assessment

Diabetic retinopathy is defined clinically as the presence of typical retinal microvascular changes in an individual with diabetes mellitus. As the disease progresses, maculopathy (macular edema and ischemia) and neovascularization of the retina (vitreous hemorrhage, retinal detachment) and iris (neovascular glaucoma) leads to vision loss. The aim of clinical assessment is to detect these serious ocular manifestations, and in their absence, to assess the risk of progression to vision-threatening disease.

Direct ophthalmoscopy enables adequate assessment of DR signs, but this is enhanced by slit-lamp biomicroscopy with a condensing lens and indirect ophthalmoscopy. Severe DR may be present without symptomatic visual impairment, therefore visual acuity assessment while important, can be misleading. Examination of the peripheral fundus is critical, particularly in patients with T1DM, to avoid missing the presence of peripheral retinal ischemia and neovascularization. Referral of patients with sight-threatening retinopathy to a specialist in ophthalmology for properly and timely treatment is key to reducing the risk of visual impairment. For patients with newly diagnosed DR, a comprehensive systemic examination by physicians is also advisable [16].

The classic retinal microvascular signs of nonproliferative DR include microaneurysms, hemorrhages, hard exudates (lipid deposits), cotton-wool spots (accumulations of axoplasmic debris within adjacent bundles of ganglion cell axons) [129], venous dilation and beading, and intraretinal microvascular abnormalities (i.e., dilated pre-existing capillaries) (Figure 61.2(a,b)). Standard clinical classifications of DR are shown in Table 61.2 [130]. This classification aims to identify stages of retinopathy that may present a significant threat to visual acuity or confer a high risk for progression to those stages, which in turn guides follow-up duration and necessity for intervention.

The appearance of retinal neovascularization is a critical change in the progression of diabetic retinopathy (Figure 61.2(c,d)). The clinical features of proliferative retinopathy may vary from a few fine new blood vessels appearing on the retina or optic disc to an increase in the size, number, and extent of these new vessels. This may be asymptomatic in the early stages but predicts that the eye is at significant risk of severe visual loss. Eyes have high risk of proliferative DR when there are new vessels of about one fourth disc area on or within one disc diameter; or new vessels at the optic disc associated with vitreous hemorrhage; or new vessels away from the disc which are greater than half disc area in size and associated with vitreous hemorrhage. These eyes have a 1-year cumulative rate of severe visual loss, defined as visual acuity less than 5/200 of 10% and a 3- and 5-year risk of 35% and 50%, respectively. Advanced proliferative disease is marked by fibrovascular proliferation, and visual loss may occur suddenly due to vitreous hemorrhage from new vessels, or tractional retinal detachment from progressive fibrosis or may be subacute due to macular ischemia and neovascular glaucoma.

Diabetic macular edema is an important sign that is assessed separately from the stages of retinopathy (Figure 61.2(f)), as it can run an independent course. Macular edema is a major cause of visual impairment in persons with diabetes and results from the abnormal collection of extracellular fluid in the retina, observed clinically as the presence of hard exudates and retinal thickening in the macula. Since not all maculopathy results in visual impairment, the ETDRS study proposed a new term "clinically significant macular edema" (CSME), which is defined as retinal thickening that involves or threatens the center of the macular, the specific definition of which is elaborated in Table 61.2.
Figure 61.2 (a) Mild nonproliferative diabetic retinopathy (b) severe nonproliferative diabetic retinopathy (c) proliferative diabetic retinopathy (d) new vessels at disc (e) proliferative diabetic retinopathy with fibrovascular proliferation (f) clinically significant macular edema.

Investigations

Advances in ophthalmic imaging have resulted in these modalities playing important roles in the screening, diagnosis, and monitoring of diabetic retinopathy.

Retinal photography serves as a useful screening tool for DR, especially where access to ophthalmologists is limited. Studies have shown that retinal photography interpreted by trained readers has high sensitivity (61–90%) and specificity (85–97%) [131], and may guide appropriate ophthalmic referral [132]. There is recent evidence to suggest that automated computer grading systems may be effective in DR screening thereby reducing the workload of manual grading [133].

Fluorescein angiography is an established modality used in clinical evaluation of DR. Microaneurysms and increased capillary permeability are the earliest detectable changes. Focal areas of capillary nonperfusion represent retinal ischemia while enlargement of the foveal avascular zone identifies macular

Table 61.2 Classification of diabetic retinopathy

International Clinical Diabetic Retinopathy Disease severity scale [130]	Defining features	ETDRS scale [18,224]	Defining features (based on 7 × 30° field stereo photographs)
No retinopathy	No retinal abnormalities	No retinopathy	No retinal abnormalities
Mild nonproliferative diabetic retinopathy (NPDR)	Microaneurysms only	Mild nonproliferative diabetic retinopathy (NPDR)	Microaneurysms only, *or* Venous loops in 1 field; retinal hemorrhages present; hard exudates or soft exudates in 1 field
Moderate NPDR	More than just microaneurysms but less than severe NPDR	Moderate NPDR	Microaneurysm and hemorrhages moderate in 4 fields or severe in 1 field or IRMA
		Moderately severe NPDR	Two out of three moderate characteristics and or one of the following: microaneurysms and hemorrhages severe in 2 or 3 fields, IRMA present in 4–5 fields or venous beading in 1 field
Severe NPDR	Any of the following: **1** More than 20 intraretinal hemorrhages in each of four quadrants **2** Definite venous beading in two or more quadrants **3** *Prominent* IRMA in one or more quadrants *and* no signs of proliferative retinopathy.	Severe NPDR	Microaneurysms and hemorrhages severe in 4–5 fields, *or* Venous beading definite in 2 fields, *or* IRMA moderate in 1 field.
Proliferative diabetic retinopathy (PDR)	Neovascularization of optic disc (NVD) or elsewhere (NVE), preretinal hemorrhage, or vitreous hemorrhage.	Mild PDR Moderate PDR	Fibrous proliferation on the optic disc or elsewhere or visible NVEs. NVE ≥1/2 disc area, *or* visible NVD, *or* Vitreous or preretinal hemorrhage and NVE < 1/2 disc area.
		High-risk PDR	NVD ≥1/4–1/3 disc area, *or* NVD < 1/4 disc area and vitreous or preretinal hemorrhage, *or* NVE ≥1/2 disc area and vitreous or preretinal hemorrhage, *or* Vitreous or preretinal hemorrhage. obscuring ≥1 disc area
Diabetic macular edema (DME)	Any apparent retinal thickening or hard exudates in posterior pole.	Macular edema	Any retinal thickening or hard exudates in posterior pole.
Mild DME	Some retinal thickening or hard exudates in the posterior pole but distant from the center of the macula.	Clinical significant macular edema	Retinal thickening at or within 500 µm of the center of the macula, *or* Hard exudate at or within 500 µm of the center of the macula *with* associated thickening of the adjacent retina, *or*
Moderate DME	Retinal thickening or hard exudates approaching the center of the macula but not involving the center.		A zone or zones of retinal thickening one disc diameter or larger, any part of which is within one disc diameter of the center of the macula.
Severe DME	Retinal thickening or hard exudates involving the center of the macula.		

ischemia. Retinal neovascularization presents as dye leakage into the vitreous. Diabetic macular edema has two main angiographic patterns: focal (from leaking microaneurysms), and diffuse (generalized breakdown of blood–retinal barrier).

Optical coherence tomography (OCT) has become an increasingly important imaging modality. It generates cross-sectional images of ocular structures by measuring the echo-time delay and intensity of reflected light, offering high-resolution, three-dimensional or cross-sectional images that closely approximate the histologic appearance of the retina [134]. OCT allows accurate and reproducible measurements of the retinal thickness, critical for monitoring progression and treatment response for diabetic macular edema. It is a more accurate and objective method of diagnosing macular edema than clinical examination, and has become an established clinical trial endpoint for treatment in diabetic macular edema. It is also useful to detect structural changes (e.g. vitreomacular traction or epiretinal membranes) that may indicate a need for surgical intervention. There is also a suggestion that it may be useful in screening for diabetic macular edema compared with nonstereoscopic retinal photography [135].

Recommended timing and frequency of screening for diabetic retinopathy

Regular dilated eye examinations can detect asymptomatic vision-threatening diabetic retinopathy effectively. In the WESDR, 14% of people with T1DM and 33% of those with T2DM developed DR within 5 years of the diagnosis of diabetes. Almost all the retinopathy cases in T1DM were mild, compared with the older participants with T2DM where 2% had proliferative retinopathy and 3% had clinically significant macular edema [46,136,137]. This suggests that DR screening should be performed at diagnosis and either yearly or second yearly thereafter in persons with T2DM. In persons with T1DM, baseline examinations could be extended to 5 years after diagnosis. The Liverpool Diabetic Eye Study, reporting retinopathy incidence in a large cohort of people with T2DM, suggests that a 3-year screening interval could be safe for patients without any evidence of retinopathy, though in patients with any sign of retinopathy, yearly or more frequent examination is recommended [138]. The most reliable and cost-effective means of screening for DR is with mydriatic digital retinal photography [139] and this has been implemented successfully in many countries resulting in cost-effective reduction of visual impairment [131,140]. Telemedicine-based digital retinal imaging may provide more cost-effective and efficacious screening for DR in diabetic patients.

Guidelines for screening and management at differing severity of DR are elaborated in Table 61.3. In practice, the timing and frequency of eye examinations in people with diabetes are often individualized. Examination at least annually is recommended for high-risk patients (e.g. those with longer duration of diabetes, poor systemic risk factor control), even in the absence of retinopathy [58]. In patients with pre-pubertal diabetes, it may be appropriate to begin retinopathy screening at puberty [73–75]. In pregnant women with nongestational diabetes, a comprehensive eye examination may be warranted during the first trimester, with follow-up throughout the pregnancy in presence of retinopathy [141]. Regular eye examinations also exert positive psychosocial effects on the care of patients with diabetes (e.g. education about risk factors, compliance) [17].

Table 61.3 Management and follow-up recommendations for diabetic retinopathy

Retinopathy severity [130]	Clinical implications	Management	Frequency of examination
No retinopathy	–	–	1–2 yearly
Mild nonproliferative diabetic retinopathy (NPDR)	5% (within 1 year) and 14% (within 3 years) progress to PDR	Optimize medical therapy of glucose, blood pressure and lipids.	Annually
Moderate NPDR	5–26% (within 1 year) and 30–48% (within 3 years) progress to PDR. 1.2–8.1% progress to high-risk PDR [225]	Refer to ophthalmologist. Optimize medical therapy of glucose, blood pressure and lipids	3–6 monthly
Severe NPDR	52% (within 1 year) and 71% (within 3 years) progress to PDR. 14.6–45.0% progress to high-risk PDR	Consider panretinal photocoagulation for patients with type 2 diabetes	3–4 monthly
Proliferative diabetic retinopathy (PDR)	Risk of severe visual loss	Indication for panretinal photocoagulation – Urgent if high-risk PDR present	Variable
Diabetic macular edema (DME)	May occur at any stage of DR		Variable
Clinically significant macular edema	Need intervention to prevent visual loss	Indication for macular laser. Consider intravitreal anti-VEGF therapy if center involving macula edema with vision loss due to DME.	Variable

Systemic treatment of diabetic retinopathy

The most effective treatment for diabetic retinopathy is prevention and this involves the optimization of systemic risk factors. Several important studies in recent years have made a significant contribution in addressing the concerns regarding systemic optimization including the target glycemic and blood pressure levels for effective prevention of retinopathy development and progression, the efficacy of various hypoglycemic and blood pressure-lowering agents, and the role of lipid-lowering agents.

1 **Glycemic control** Hyperglycemia is the key initiator in the pathogenesis and development of diabetic retinopathy. The DCCT and the United Kingdom Prospective Diabetes Study (UKPDS) are the key studies providing definitive evidence that tighter control of glycemia (HbA1c 7%) reduces the risk of development and progression of DR in both T1 and T2DM [60,142,143]. There is evidence of a small risk of initial worsening of retinopathy at the onset of therapy, but the long-term benefits outweigh this risk [144]. Each percent reduction in HbA1c (e.g. from 9% to 8%) lowers the risk of retinopathy by 30–40% and the effect is long-lasting even if subsequent metabolic control deteriorates later in life, an effect termed "metabolic memory" [145]. In keeping with these findings, a recent meta-analysis shows a graded relationship between the level of glycemia and frequency of retinopathy signs [146].

There is recent evidence to show that there is a limit to the benefit of further lowering of glycemic levels in persons with diabetes. The Action in Diabetes and Vascular Disease (ADVANCE) trial [147], demonstrated that aggressive glycemic control (HbA1c <6.5%) did not significantly impact on retinopathy development or progression in T2DM [147]. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial showed that while intensive therapy for glycemic control did reduce macrovascular and microvascular events and progression of DR, it was also associated with increased episodes of severe hypoglycemia and increased mortality [148], although the cause of unexpected excess deaths remains unclear [149]. This suggests that in older patients and in those with established cardiovascular disease, perhaps glycemic targets should be less strict.

The Veterans Affairs Diabetes Trial (VADT) also recently reported that after 5-years follow-up, intensive glycemic control (HbA1c 6.9%; comparable to the DCCT and UKPDS) did not yield any significant benefit on the retinopathy outcomes [150]. While these findings contrast with those from the UKPDS, they could be related to the population in the VADT having more males (97%), shorter length of follow-up, and later initiation of therapy. Although it was not statistically significant, the rate of retinopathy progression in the VADT was modestly lower in the intervention group than in the control group (17% vs. 22%; $p = 0.07$), so that a delayed benefit of intensive glycemic control, as found in previous studies [151,152], cannot be excluded.

Recent analysis from the UKPDS and DCCT trials have suggested that the protective effect of intensified blood glucose control, especially early in disease, has a sustained effect over time. This "metabolic memory" effect persists even if glycemic control is less intensive later in the course of disease. In the DCCT, follow-up analysis showed that 4 years after the end of the trial, 17.8% of patients who were originally randomized to intensified glycemic control had progression in DR compared with 48.9% of those randomized to the conventional group; and at 10 years progression was found in 35.8% compared with 60.6% [145]. In the UKPDS, at 10 years follow-up, although the between group differences in glycated hemoglobin levels were lost after the first years, in the intensively treated group, the relative risk reduction persisted at 24% for microvascular disease compared with the less intensive group [153].

2 **Blood pressure control** Epidemiologic studies and clinical trials found that hypertension is a major modifiable risk factor for diabetic retinopathy [58]. Hypertension leads to increased retinal blood flow and mechanical damage and stretching of vascular endothelial cells, stimulating the release of VEGF which contributes to progression of DR [154,155]. Each 10 mmHg increase in systolic blood pressure is associated with an approximately 10% excess risk of early DR and a 15% excess risk of proliferative retinopathy [156,157]. In the UKPDS, tighter blood pressure control reduced the risks of retinopathy progression by about one third, visual loss by half, and need for laser treatment by one third in people with T2DM [61,155]. However, these benefits are not sustainable without ongoing and long-term maintenance of blood pressure control [158].

Clinical trials have shown that renin-angiotensin system inhibitors may reduce the incidence and progression of DR beyond their blood pressure-lowering effects compared with other antihypertensive drugs. The EURODIAB Controlled Trial of Lisinopril in Insulin-Dependent Diabetes Mellitus (EUCLID) showed that lisinopril reduced the risk of retinopathy progression by 50% and proliferative retinopathy by 80% [159]. The EUCLID, however, was limited by treatment arm differences in baseline glycemia and by its short (2-year) follow-up. The Diabetic Retinopathy Candesartan Trials (DIRECT) and the Renin-Angiotensin System Study (RASS) supported these findings. In the DIRECT trials, candesartan reduced the risk of retinopathy development by 18% to 35% in T1DM, and increased regression of retinopathy by 34% in T2DM [160–162]. In the RASS, enalapril and losartan reduced the risk of retinopathy progression by 65% and 70%, respectively, in T1DM, independent of the changes in blood pressure over the period of the trial [163].

In the 10-year post trial monitoring of patients from the UKPDS, difference in blood pressure between the tight and less tight blood pressure control regimens disappears within 2 years after termination of the trial. In contrast to the sustained benefit of early glucose control, the risk reductions found during the trial for microvascular disease were no longer significant during the follow-up. This suggests that good blood pressure control must be continued if the benefit of reduced incidence and progression of retinopathy is to be maintained [158].

3 Lipid-lowering therapy Observational studies support a role for dyslipidemia in the pathogenesis of diabetic retinopathy [58]. The DCCT showed that the severity of retinopathy was associated with increasing triglycerides and lower levels of HDL-cholesterol [164]. A high total to HDL-cholesterol ratio and elevated LDL-cholesterol were also associated with the development of clinically significant macular edema [165]. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial showed that fenofibrate, a lipid-modifying agent, reduced the need for laser treatment of vision-threatening DR by 31% in patients with T2DM over 5 years [62]. The ACCORD study reported a 40% reduction in the odds of having progression of retinopathy over 4 years afforded by fenofibrate combined with simvastatin compared with simvastatin alone, further supporting the efficacy of fenofibrate [63,166]. Interestingly, this finding did not appear to be secondary to changes in the traditional serum lipid profile [167]. Experimental studies have suggested a number of possible mechanisms for the action of fenofibrate which involve lipid and nonlipid pathways, including upregulation of apo A-I, antiapoptotic activity, oxidative stress, inflammation, protective effects on blood–retinal barrier breakdown, and neuroprotective effect [168,169]. These results suggest that fenofibrate may be beneficial in the early stages of DR.

4 Multifactorial intervention The Steno-2 study investigated the effect of intensive multifactorial intervention, with tight glucose regulation and the use of renin-angiotensin system blockers, aspirin, and lipid-lowering agents, in patients with T2DM and microalbuminuria [170]. The Steno-2 study encompassed treatment goals similar to those recommended in the American Diabetes Association guidelines. It showed that after 8 years of intensified, target-driven intervention that aimed to control multiple vascular risk factors the risk of retinopathy was reduced by 58% [170]. The differences in the levels of risk factors between the controlled and intervention groups were no longer significant 5 years later; however, the beneficial effects on retinopathy were sustained [170]. This is in keeping with the "metabolic memory" findings seen in the DCCT [145], and UKPDS [153] reinforcing the importance of early and strict implementation of multifactorial interventions to prevent the development and progression of DR.

5 Emerging medical treatments Understanding the biochemical pathways in the pathogenesis of diabetic retinopathy, various novel systemic therapies are being developed. Protein kinase C is a key mediator resulting in increased retinal neovascularization and vascular permeability. Ruboxistaurin, a well-tolerated selective protein kinase C inhibitor, has been shown in initial trials to reduce the risk of progression and need for laser treatment for diabetic macular edema [171–174], and could reduce visual impairment from long-standing macular edema [175]. However, additional trials are needed to verify these findings. Diabetes results in accumulation of AGE in the retina and the DCCT showed that AGE levels from skin biopsy may predict retinopathy progression [176,177]. A clinical trial in T1DM suggests that patients treated with Pimagedine, an aminoguanidine that inhibits the formation of AGE, has been shown in a clinical trial involving T1DM to reduce the likelihood of retinopathy progression [178].

Ocular therapy

Laser photocoagulation has long been established as the gold standard for ophthalmic therapy for vision-threatening diabetic retinopathy. Timely and appropriate laser treatment is effective in preventing visual loss but has significant ocular side effects since photocoagulation is ultimately a destructive procedure. Furthermore, reversal of visual loss is uncommon even with adequate treatment. Recently, new and more effective therapeutic strategies aimed at improving vision have been developed (see Table 61.4).

Laser photocoagulation
Laser therapies for diabetic retinopathy are panretinal photocoagulation (PRP) for proliferative retinopathy and macular (focal/grid) laser photocoagulation for diabetic macular edema. In PRP, the laser burns are placed over the entire retina sparing the central macula in order to promote regression and arrest progression of retinal neovascularization, possibly by reducing ischemia-driven VEGF production [95]. The Diabetic Retinopathy Study (DRS) and the Early Treatment Diabetic Retinopathy Study (ETDRS), two landmark clinical trials in the management of DR, established PRP as the primary treatment for proliferative retinopathy and severe nonproliferative retinopathy.

In the DRS, PRP reduced the risk of severe visual loss (visual acuity ≤5/200) by 50% over 5 years in more than 1758 patients with proliferative disease [179]. In the ETDRS of 3711 patients with less severe DR, early PRP reduced the risk of progression to high-risk proliferative retinopathy by 50% [180]. The DRS and ETDRS findings have been further reinforced by subsequent clinical trials [58]. The adverse effects of PRP include difficulty with light–dark adaptation (25%), a small decrease in visual acuity (10%), and peripheral visual loss (5%), which may impair night vision and affect driving [58]. Other adverse effects include changes in color vision and worsening of macular edema [58]. Both DRS and ETDRS indicate that less severe stages of DR may not benefit from laser treatment, especially given the risk of adverse effects.

In the ETDRS, macular laser reduced the risk of moderate visual loss from clinically significant macular edema by 50% [181]. The Diabetic Retinopathy Clinical Research Network (DRCRnet) showed that about 30% of patients treated with macular laser gained better vision (≥10 letters) over a 2-year period [182]. As these studies included a mixture of patients with focal or diffuse macular edema, the relative efficacy of laser treatment for specific patterns of macular edema remains undetermined.

Table 61.4 Summary of treatments for diabetic retinopathy

Intervention	Recommendation	Evidence
Diabetic macular edema (DME)		
Focal laser	Focal laser therapy is recommended in eyes with CSME and has long-term visual acuity benefits. Treatment should be considered to DME threatening the center of the macula.	A, I
Intravitreal anti-VEGF agents	Intravitreal anti-VEGF therapy is effective as primary treatment for most cases of DME and is superior in the short term to laser treatment for visual acuity again. It is recommended for center involving DME with loss of vision secondary to DME.	A, I
Intravitreal steroids	Intravitreal steroids are not effective as primary treatment for most cases of DME, but may have a role in diffuse DME unresponsive to focal laser.	A, II
Vitrectomy	Vitrectomy may have a role in selected cases of diffuse severe DME unresponsive to focal laser, especially in the presence of vitreomacular traction.	B, III
Medical therapies	There is currently insufficient evidence to recommend the routine use of PKC inhibitors and other treatments.	C, III
Diabetic retinopathy (DR)		
Panretinal photocoagulation (PRP)	PRP is recommended in cases with proliferative DR. Treatment should be promptly institutes if high-risk features are present.	A, I
	PRP is recommended in severe nonproliferative DR if any difficulty or delay in follow-up is anticipated or there are associated risk factors or signs of progression, especially in patients with type 2 diabetes.	A, II
Vitrectomy	Early vitrectomy is recommended within 3 months in patients with type 1 diabetes with severe vitreous hemorrhage and significant DR. Type 2 diabetics benefit from vitrectomy for persistent vitreous hemorrhage, although the benefit of early vitrectomy is less. Vitrectomy should be considered in eyes with severe PDR not responsive to extensive PRP, associated with traction involving the macula, or both.	B, II

Intraocular antivascular endothelial growth factor (VEGF) agents

VEGF is a potent mediator for abnormal retinal vessel growth and leakage, making it an important therapeutic target in diabetic retinopathy [94]. Intraocular VEGF levels correlate closely with hypoxia and active neovascularization, and its levels decline after successful laser photocoagulation [95]. In addition, inhibitors of VEGF activity ameliorate ischemia-induced retinal neovascularization in animal models [94,96]. These findings all support the theory that anti-VEGF agents could arrest, or even reverse, proliferative retinopathy and macular edema.

Several agents have been evaluated in clinical trials of anti-VEGF therapy. These agents are delivered by injection directly into the vitreous of the eye (intravitreal injection), thus theoretically maximizing local efficacy and minimizing systemic adverse effects. The two most widely used anti-VEGF agents are ranibizumab, a humanized, monoclonal VEGF antibody fragment and bevacizumab, a humanized monoclonal antibody to VEGF. Newer agents are being developed including aflibercept, a soluble decoy receptor fusion protein that binds VEGF. Most trials have demonstrated benefits with the use of intravitreal anti-VEGF agents, either alone or combined with laser or intravitreal corticosteroids, for both diabetic macular edema (DME) and proliferative retinopathy or as an adjunctive therapy for vitrectomy. The RISE and RIDE trial, two phase 3 randomized trials assessing ranibizumab for diabetic macular edema found that a significantly greater proportion of patients receiving either 0.3 mg or 0.5 mg ranibizumab (33.6% to 45.7%) gained 15 letters or more in best corrected visual acuity compared with sham injection (12.3 to 18.1%) at 2 years, demonstrating a rapid and sustained improvement in vision with reduced risk of further vision loss and improved macular edema from ranibizumab with low rates of ocular and nonocular harm [183]. The RESTORE trial reported a 12-month visual acuity improvement of 6.1 letters in patients treated with ranibizumab plus sham laser and 5.9 letters in ranibizumab combined with laser therapy compared with 0.8 letters in laser plus sham injection [184]. The Diabetic Retinopathy Clinical Research Network (DRCRnet) demonstrated that patients treated with ranibizumab plus prompt laser or deferred laser had significantly better visual outcomes (9 +/− 12 letter gain) at 1 year compared with those treated with sham injections plus prompt laser (3 +/− 13 letter gain), and this difference was maintained at 3-year follow-up [185,186]. The FDA has approved monthly 0.3 mg ranibizumab intravitreal injections for DME. An expert panel recommended that ranibizumab was indicated in the treatment of DME when both center involvement and significant visual loss (20/40 or worse) due to DME were present [187]. The off-label use of bevacizumab in DME is common due to its lower cost. The DRCRnet group

examined the use of bevacizumab for DME in a phase 2 clinical trial and found that subjects who received bevacizumab alone had greater visual improvement compared with laser alone. The combination of bevacizumab with laser had no short-term benefit compared with bevacizumab alone [188]. The BOLT study compared bevacizumab with laser in DME patients with visual acuity of 20/40 to 20/320 and found at 2 years that the bevacizumab arm had a median gain of 9 letters compare with a 2.5 letter gain in the laser arm [189]. A recent systematic review examining the relative clinical effectiveness of ranibizumab and bevacizumab in DME found no statistically significant difference in the improvement in best corrected visual acuity (BCVA) of more than two lines, the mean change in best corrected visual acuity or the mean change in central macular thickness between the two drugs [190]. The role of combination therapy with both anti-VEGF injections and laser remains to be defined. In the current trials, no additional benefit has been shown with adding laser to ranibizumab. The RESTORE and DRCRnet trials may suggest that combination therapy may have inferior visual acuity outcomes compared with ranibizumab injection alone. The DA VINCI study, a phase 2 clinical trial of Afibercept in eyes with center-involved DME, found that various regimens of afibercept at 52 weeks resulted in a 9–13 letters gain in BCVA compared with a 1.3 letter loss of BCVA in eyes treated with laser. This benefit was also seen in the group given 8 weekly treatments after 3 initial doses suggesting that less frequent treatments may be required given the longer half-life of Afibercept [191].

Ocular and systemic safety of intraocular anti-VEGF therapy

Although anti-VEGF therapy has promising clinical application in the management of diabetic retinopathy, its long-term safety in patients with diabetes has not yet been established [94]. Local adverse effects of intravitreal anti-VEGF therapy include cataract formation, retinal detachment, vitreous hemorrhage, infection, and potential loss of neural retinal cells [94].

Although injected intravitreally, significant levels of anti-VEGF agents injected may pass into the systemic circulation [94,192]. Thus, systemic inhibition of angiogenesis is a potential risk, which could compromise critical vascular responses to ischemic events in patients with diabetes. Other unwanted systemic side effects may include hypertension, proteinuria, and impaired wound healing [94], which are also of relevant concern for patients with diabetes. Prolonged systemic exposure to anti-VEGF agents, due to the lengthy half-life of some agents and the need for repeated administration, may be associated with higher risks of systemic vascular complications, such as stroke and nonocular (e.g. gastric, renal) hemorrhage [192,193]. Although clinical trials on the use of intravitreal anti-VEGF therapy for treatment of age-related macular degeneration generally show low (0.6–1.2%) incidence of stroke [194], patients with DR may be at higher risk due to pre-existing diabetes-related vascular disease [16]. A systematic review of

studies examining the use of anti-VEGF therapy in DME found no consistent increase in adverse events with either ranibizumab or bevacizumab although these trials were underpowered to detect differences in adverse events [190]. Meta-analysis of combined data from all ranibizumab trials of patients receiving monthly injections showed that the incidence of cerebrovascular accidents was 2.2% in the ranibizumab-treated subjects versus 0.7% in sham-treated subjects ($p = 0.045$) [195]. It has been suggested that ranibizumab may have a lower risk adverse effects compared to bevacizumab due to its shorter systemic half-life. The comparison in the age-related macular degeneration treatment trials found that the proportion of serious systemic adverse events was higher with bevacizumab than with ranibizumab (24.1% vs. 19.0%; RR = 1.29; 95% CI 1.01–1.66) [196]. A safety review and meta-analysis of bevacizumab and ranibizumab found that the proportion of patients with serious infections and gastrointestinal disorders was higher with bevacizumab than with ranibizumab (RR = 1.3; 95% CI 1.0–1.7), although arterial thromboembolic events were equally distributed among the groups [197]. Thus, treatment of DR with these agents must involve both clinicians and patients recognizing and assessing the potential risks and benefits.

Intraocular steroids

Inflammation has been shown to play an important role in the pathogenesis of diabetic retinopathy [106]. Although intraocular administration of corticosteroids has been widely used to treat diabetic macular edema [182,198,199], there has been ongoing debate regarding its use due to the potential side effects. A systematic review of seven randomized clinical trials involving 632 eyes with diabetic macular edema suggests that eyes treated with intravitreal triamcinolone, a long-acting corticosteroid, had modest improvement in visual acuity [198].

The DRCRnet conducted a multicenter randomized clinical trial in the US that compared intravitreal triamcinolone with macular laser for treating diabetic macular edema [182]. Eyes treated with intravitreal triamcinolone demonstrated a better treatment response compared with eyes treated with laser at 4 months. However, this difference disappeared after 1 year and by 2 years, eyes treated with laser had significantly better vision than eyes treated with intravitreal triamcinolone. These findings remained unchanged after 3 years of follow-up [200]. Intravitreal triamcinolone was also found to be frequently associated with significant ocular adverse effects, including secondary raised intraocular pressure and cataract progression [182,200].

The DRCRnet did not address the role of intravitreal triamcinolone in eyes that do not respond well to laser (diffuse or refractory diabetic macular edema). A recent systematic review reported that while intravitreal triamcinolone improves vision in eyes with refractory diabetic macular edema in the short term (3 months), the benefits are not long-lasting [199]. Nevertheless,

intravitreal triamcinolone may have a role as an adjunctive therapy to laser [201].

A trial on sustained release steroid implants showed some efficacy in improving visual acuity in eyes with DME [198]. Long-acting dexamethasone implants have shown improvement in vision for DME in vitrectomized eyes and for patients with persistent DME. The adverse effects may be less frequent than seen with triamcinolone but there were still a significant number of eyes developing raised intraocular pressure requiring medical treatment [202]. Sustained delivery of fluocinolone acetonide vitreous inserts has also been shown to provide sustained improvement in visual acuity in patients with persistent DME for up 3 years compared with sham injections, although there was an increased incidence of cataract in phakic patients and glaucoma requiring incisional surgery in the fluocinolone implant groups [203].

Surgical intervention
Vitrectomy is the surgical treatment for blinding complications of advanced retinopathy including persistent vitreous hemorrhage, tractional retinal detachment, and persistent macular edema with vitreous traction. It can reduce the risk of retinal neovascularization and macular edema but conversely may incite harm by increasing the risk of iris neovascularization and cataract formation [204].

The Diabetic Retinopathy Vitrectomy Study (DRVS) was the largest randomized clinical trial that evaluated the indications and timing of vitrectomy for the management of advanced proliferative retinopathy [205,206]. In the DRVS, patients with T1DM with severe vitreous hemorrhage were more likely to achieve desirable visual outcome (visual acuity 20/40) if early vitrectomy was performed (within 1 to 6 months), as compared to late vitrectomy (at 1 year). However, this benefit was not observed in patients with T2DM. This could have been related to more frequent macular ischemia in patients with T2DM. Although data from the DRVS are still valuable for clinical guidance, the threshold for performing vitrectomy has lowered in recent years due to advances in vitreoretinal surgery, including smaller gauge instruments and the ability to apply retinal laser during surgery [58].

Vitrectomy has also been suggested for diabetic macular edema refractory to laser therapy, particularly if there is evidence of macular traction (e.g. vitreomacular traction, epiretinal membrane, tractional retinal detachment close to the macula) [204]. A few trials have demonstrated some benefits of vitrectomy combined with peeling of the internal limiting membrane, the innermost layer of the retina, for diffuse or refractory diabetic macular edema [58].

Cataract surgery
People with diabetes have a higher risk of developing cataract requiring surgery [1]. However, cataract surgery may exacerbate macular edema [207], and retinopathy progression [208,209].

Thus, laser treatment for patients with DR prior to or promptly after cataract surgery may be useful. Clinical trials also suggest that intravitreal anti-VEGF agents during cataract surgery may be an effective adjunctive therapy to optimize visual outcome after surgery in selected cases [210,211].

Other ocular complications

Diabetic retinopathy may be the major cause of visual loss in diabetic patients; however, diabetes is also associated with a range of ocular disease which can also cause visual impairment and morbidity.

Cataract
Multiple studies have shown the association between cataracts and diabetes [212,213]. The prevalence of cataract is increased in persons with diabetes and the risk of cataract increases with longer duration of diabetes and poorer metabolic control. Deposition of advanced glycation end-products in the lens has been postulated as one possible mechanism for diabetic cataract. Cataract is a major cause of visual impairment in persons with diabetes. Although the overall outcome with cataract surgery is excellent, persons with diabetes have poorer visual outcomes compared with nondiabetic subjects after cataract surgery especially in eyes with pre-existing macular edema or proliferative DR [1]. Studies have also suggested that individuals with diabetes are at greater risk of postoperative endophthalmitis, a severe potentially blinding intraocular infection [214].

Refractive error
Diabetic subjects can present with fluctuating refractive error. This is due to accumulation of sorbitol in the lens as a result of hyperglycemia and increased aldose reductase activity. This results in lens swelling with change in refractive error which may fluctuate with improved glycemic control [215].

Optic disc
Anterior ischemic optic neuropathy (AION) is an ischemic vascular condition involving the optic nerve head which presents with acute, monocular, painless visual loss with optic disc swelling. Diabetic microvascular disease is postulated to contribute to the ischemia and up to 25% of patients with AION have a history of diabetes [216].

Diabetic papillopathy presents with mild visual loss and optic nerve swelling which should be distinguished from other causes of disc swelling such as papilledema and malignant hypertension. Diabetic papillopathy is a risk factor for progression of DR and may precede the development of AION [1].

Ocular motility disorders
Diabetes can cause mononeuropathies involving the third, fourth, or sixth cranial nerves, and is responsible for 25–30% of

patients aged 45 years and older who develop acute extraocular muscle palsy [217]. These patients present with binocular diplopia, and in third cranial nerve palsies, the absence of papillary involvement distinguishes it from surgical causes such as intracranial aneurysms or tumors. Recovery from diabetic cranial nerve mononeuropathies usually occurs within 3 months [218], but recurrences or subsequent involvement of other cranial nerves is common. Further investigations to exclude compressive lesions are advised in the presence of other focal neurologic deficits, progressive deterioration, or palsies occurring in young patients.

Glaucoma

Glaucoma is a progressive optic neuropathy associated with characteristic optic disc changes and visual field defects. Elevated intraocular pressure is the major modifiable risk factor although it may not always be present. Several epidemiologic studies have reported that primary open angle glaucoma is more common among individuals with diabetes although this finding has not been found in other studies [219]. The risk of glaucoma has been reported to be 1.6 to 4.7 times higher in individuals with diabetes compared to nondiabetics [1]. This increased risk may be related to optic nerve damage secondary to impaired microvascular circulation; or concomitant cardiovascular risk factors that affect vascular perfusion to the optic nerve head. Patients with primary angle closure glaucoma are more likely to have abnormal glucose levels than either those with primary open angle glaucoma or healthy controls. This association between primary angle closure glaucoma and diabetes may be related to systemic autonomic dysfunction or increased lens thickness secondary to hyperglycemia.

Neovascular glaucoma has been consistently associated with diabetes, with proliferative diabetic retinopathy accounting for 32–43 % of cases [1]. Neovascularization of the iris occurs secondary to ischemic DR with the release of growth factors such as VEGF. This fibrovascular proliferation disrupts normal aqueous outflow resulting in raised intraocular pressure and neovascular glaucoma. Regression of neovascularization can occur following early treatment with panretinal photocoagulation [220]; however, visual prognosis is usually guarded.

Corneal disorders

Diabetes is known to affect the corneal epithelium leading to corneal erosion, persistent epithelial defects, or corneal ulcers. A reduction of hemidesmosomes, which attach epithelial cells to the extracellular matrix, may contribute to weakness in the adhesion of diabetic corneal epithelium to the underlying stroma [221]. Epithelial defects and recurrent erosions have been reported to occur after photocoagulation and vitrectomy. Persons with diabetes also often have reduced corneal sensation related to peripheral neuropathy and limbal vasculopathy [222]. This deficit may predispose to bacterial corneal ulcers and complications with contact lens use.

Other retinal conditions

Central and branch retinal vein occlusion may occur in greater frequency in diabetic individuals although epidemiologic studies have not shown a consistent relationship [1]. Retinal vein occlusion must be distinguished from DR in persons with diabetes who present with acute visual loss and unilateral retinal changes. The prevalence of diabetes in patients with central retinal artery occlusion is reported to be much higher than in the age-matched general population [223]. Retinal artery occlusion presents with sudden unilateral severe visual loss and should be referred immediately to an ophthalmologist for management, although visual prognosis is poor even with treatment.

Future directions

In spite of our growing understanding of the pathophysiologic and risk factors for diabetic retinopathy, much remains unanswered. Traditional risk factors only account for a small proportion of the variation in retinopathy risk in persons with diabetes. Novel markers, pathophysiologic pathways or genetic determinants need to be identified to explain the remaining variation in risk. Although new treatments have emerged in the systemic and ocular management of DR, the most efficacious clinical application of these modalities has yet to be defined. Fenofibrate has been shown to reduce the risk of retinopathy, but further studies are needed to define the best responders in order to guideline when and to whom the medication should be prescribed. Antivascular endothelial growth factors have heralded a paradigm shift in the treatment of DME; however, the lack of sustained effect and the need for repeated injections remain unsatisfactory. The development of longer acting therapies or less invasive means of drug delivery is needed to address these concerns. Developments in telemedicine and nonmydriatic screening will allow us to improve the early detection and prevention of vision-threatening diabetic retinopathy.

[2]Department of Endocrinology & Diabetes, St Vincent's Hospital Melbourne, Victoria, Australia
[3]University of Melbourne, Victoria, Australia

Key points

- Diabetic nephropathy (DN), responsible for half the burden of end-stage renal disease (ESRD) in westernized societies, affects approximately one third of patients with T1DM or T2DM. Ninety percent of diabetes-related ESRD occurs in patients with T2DM, with this proportion likely to increase due to the obesity epidemic.

- DKD is initiated by inadequate glycemic control. Intensive glycemic control prevents the onset of DN but current evidence suggests it is less effective in later stages of DN.

- DKD progression is promoted chiefly by hyperglycemia and hypertension, with control of blood pressure assuming greater importance in later stages. In overt DN, approximately 30% of the renoprotective effect of antihypertensive therapy is attributable to renin-angiotensin system (RAS) inhibition.

- Duration of diabetes, reflecting cumulative metabolic and hemodynamic stress, is a major determinant of the onset of DN. Rapid progression of DN is associated with puberty in T1DM, and with ethnicity (nonmodifiable) and socioeconomic status (modifiable) in T2DM.

- DKD is described by elevations in albumin excretion rate (AER) and/or decreases in glomerular filtration rate (GFR). Classically, DN is defined by a rise in AER to clinically detectable concentrations heralding in a decline in GFR. However, in one quarter of patients with DKD, a decline in GFR occurs in the absence of an increase in AER.

- In overt DN (macroalbuminuria), a greater decrease in AER during the first 3 months of antihypertensive therapy predicts a slower rate of GFR decline long term. This has not been shown in patients with early DKD/incipient DN (microalbuminuria).

- In T2DM patients with hypertension and microalbuminuria, simultaneous intensive control of glycemia, blood pressure, and dyslipidemia decreases progression of DN and cardiovascular (CV) events by 30–50% over 4–8 years.

- RAS inhibition with either an ACE inhibitor or an ARB results in equivalent effects on AER and GFR decline. Most patients will require multiple antihypertensive agents to achieve a target SBP <140 mmHg. However, combination of an ACE inhibitor with an ARB has no additive effect on GFR decline and increases side effects.

- DKD is often associated with CV disease or additional CV risk factors. In these high-risk patients, rapid and intensive lowering of glycemia (attained HbA1c 6.4%, 46 mmol mol^{-1}) or blood pressure (attained SBP 119 mmHg) may increase the risk of death or acute renal failure, respectively.

- Renal biopsy should be considered in patients with unusually rapid increases in AER, macroalbuminuria despite short duration of diabetes, an abnormal urinary sediment, or evidence of systemic illness with potential renal involvement.

Definition and classification of diabetic kidney disease (DKD)

Diabetic kidney disease (DKD) encompasses a spectrum of clinical and histopathologic chronic kidney disease (CKD) found in people with diabetes mellitus, including both type 1 (T1DM) and type 2 (T2DM). The traditional descriptive term for renal disease in people with diabetes, diabetic nephropathy (DN), is defined specifically as the presence of persistent, clinically detectable proteinuria, associated with an elevation in blood pressure (BP) and a decline in glomerular filtration rate (GFR). However, subclinical proteinuria—termed microalbuminuria—has been recognized as a definable early stage in the natural history of rising albuminuria in DKD. Microalbuminuria is defined according to an albumin excretion rate (AER) of 20–200 µg min^{-1} (30–300 µg d^{-1}) or an albumin to creatinine ratio (ACR) of 2.5–25 mg mmol^{-1} in males and 3.5–35 mg mmol^{-1} in women (Table 62.1). The development of persistent microalbuminuria—that is, microalbuminuria detected in at least two out of three consecutive 24-hour urine

Table 62.1 Classification of albuminuria in people with diabetes

	AER		ACR (mg mmol^{-1}/mg g^{-1})	
	µg min^{-1}	mg d^{-1}	Females	Males
Normoalbuminuria	<20	<30	<3.5/<35	<2.5/<25

AER, albumin excretion rate; ACR, albumin to creatinine ratio.

collections or early morning midstream samples—has been equated to incipient nephropathy, although more recently it has also been recognized as an important risk marker of cardiovascular disease and death in people with diabetes.

The combined contributions of albuminuria and GFR to the prognosis of kidney disease, including DKD, are reflected by the development of a two-dimensional composite ranking system, based on renal and cardiovascular risk [1]. According to this classification, albuminuria is ranked in three ACR categories, normo-, micro-, and macroalbuminuria and GFR ranked in five estimated GFR (eGFR) categories (G1–5) as shown in (Table 62.2). The term DKD will generally be used throughout this chapter instead of the term DN, unless reference is specifically made to studies which have involved experimental models or subjects with hypertension and proteinuria that fulfill the criteria for the original description of overt nephropathy.

Aetiology of DKD

In T1DM, the initiator of DKD is hyperglycemia, whereas elevated blood pressure (BP) is a progression promoter as well as a consequence of DKD. Dyslipidemia has not been shown to be an initiator or pathogenetic promoter of DKD. In T2DM, DKD is also initiated by hyperglycemia but hypertension, atherosclerosis, and aging-related intrarenal vascular disease may contribute as progression promoters.

Although subtle changes in renal function and structure may develop in most subjects with diabetes, clinically overt DKD

Table 62.2 Classification of chronic kidney disease (CKD) incorporating albuminuria category (albumin to creatinine ratio) and estimated glomerular filtration rate (eGFR) stage, proposed in the Kidney Disease: Improving Global Outcomes (KDIGO) Controversies Conference Report 2012 [62].

CKD Classification as proposed by KDIGO Controversies Conference Report 2012			Albuminuria stages, description and range (mg/g:mg/mmol)				
			A1		A2	A3	
			Optimal and high normal		High	Very high and nephrotic	
GFR Stages description and range (ml/min per 1.73m^2)			<10 <1	10–29 1–2.9	30–299 3–30	300–1999 30–199	>2000 >200
G1	High and Optimal	>105					
		90–104					
G2	Mild	75–89					
		60–74					
G3a	Mild-moderate	45–59					
G3b	Moderate	30–44					
G4	Severe	15–29					
G5	Kidney Failure	<15					

Note: The accuracy of the albumin to creatinine ratio (ACR) in stage A2 (microalbuminuria) can be improved by allowing for the greater muscle mass in men, which leads to higher urinary creatinine concentrations. Sex-specific ACR ranges in stage A2 are as follows:

Men	Women
2.5–25	3.5–35 mg mmol^{-1}
25–250	35–350 mg g^{-1}

develops in approximately one in three Caucasian subjects with either T1DM or T2DM. By contrast, the risk of DKD in T2DM is often increased in other ethnic groups, including a 5–10-fold higher risk in Pima Indians and Indigenous Australians. In Indigenous Australians, albuminuria often precedes onset of diabetes, suggesting a different pathogenetic pathway.

Recent evidence indicates that genetic, epigenetic, and dietary factors may influence the development and progression of DKD. Some families appear more susceptible to DKD than others [2], and recent studies have linked specific gene variants with different DKD phenotypes. For instance, the gene variants associated with an increase in albuminuria may differ from those associated with a decrease in GFR in patients with T2DM and advanced DKD.

In T1DM patients with DKD, impaired GFR has been associated with several variants in genes controlling matrix metalloproteinases and with endothelial nitric oxide synthase (eNOS). In T2DM, impaired GFR has been linked with variants in the engulfment and cell mobility (*ELMO 1*) gene and the gene for the key proinflammatory cytokine, interleukin-6 (IL-6).

Despite these advances, both candidate gene studies and genome-wide linkage scans have so far failed to identify a major gene that explains the strong familial clustering of DKD in T1DM and T2DM. By contrast, major advances have occurred in understanding the genetics of nondiabetic kidney disease in African Americans.

First, hypertension-associated end-stage renal disease (ESRD) is substantially related to polymorphisms in the nonmuscle myosin heavy chain 9 gene (*MYH9*) and this may explain the poor response to blood pressure control in African Americans with hypertensive nephrosclerosis. Second, a single gene variant in the apolipoprotein L1 gene (*APOL1*) has been shown to fully account for excess rates of nondiabetic kidney disease in African Americans. Whether gene variants in *APOL1* influence the course of DKD in African American or in other ethnic groups is not yet clear.

Epigenetic factors represent another mechanism linking genes, the environment and DKD [3]. Potential epigenetic markers for DKD progression have been identified by comparing DNA methylation in patients with T2DM, with or without DKD. Epigenetic differences leading to lower levels of DNA methylation in peripheral blood leukocytes from patients with DKD were associated with a predisposition to ESRD. However, prospective studies are required to show that epigenetic factors predict DKD.

Dietary factors may impair renal function in patients with diabetes. Obesity predisposes to focal sclerosing glomerulonephritis and may therefore contribute to a decline in GFR, especially in patients with T2DM. High-protein diets may decrease GFR in subjects with preexisting renal impairment. Exogenous advanced glycation end-products (AGEs) as well as advanced lipid peroxidation end-products (ALEs) may also contribute to renal damage in patients with diabetes [4].

The kidney is an important regulator of AGE metabolism and circulating AGE levels are markedly elevated in patients with renal insufficiency with or without diabetes. This applies in particular to low molecular weight AGEs which are not bound to proteins and may damage target cells by binding to cellular AGE receptors (RAGE) and promoting vascular dysfunction [5].

The cellular mechanisms responsible for renal damage include activation of RAGE, which triggers increases in protein kinase C (PKC), nuclear factor kappa B (NFκB), transforming growth factor-β (TGF-β), and connective tissue growth factor. RAGE activation induces glomerular matrix production and increases oxidative stress through both cytosolic and mitochondrial superoxide production [6]. Studies in experimental diabetes have also shown that RAGE activation promotes epithelial-mesenchymal transdifferentiation of renal tubular cells, thereby contributing to interstitial fibrosis.

Immunohistochemical studies in subjects with diabetic or nondiabetic kidney disease have shown that AGEs accumulate in the mesangium and the glomerular capillary wall [7]. While it is not yet clear whether AGEs contribute to disease progression as opposed to being markers of disease severity, there is preliminary evidence supporting a pathogenetic role for exogenous AGEs. In a group of diabetic subjects, short-term dietary AGE restriction was associated with a significant reduction in markers of inflammation, plasma C-reactive protein, and peripheral mononuclear cell tumor necrosis factor-α (TNF-α). Furthermore, urinary excretion of the AGEs carboxymethyllysine (CML) in T1DM and methylglyoxal in T2DM has been associated with increases in albuminuria.

In summary, the kidneys excrete AGEs and are also targets for AGE-induced injury. Long-term exposure to a diet high in AGEs (as occurs with prolonged or high temperature cooking of proteins) may therefore contribute to the rate of progression of renal impairment in the elderly with or without coexisting diabetes. The postulated contributions of oxidative stress, growth factors, inflammation, AGEs, and intraglomerular pressure to the development and progression of DKD are summarized in Figure 62.1.

Recent studies in normoalbuminuric patients have shown that circulating markers of inflammation such as TNF-α receptors (sTNFR1 and sTNFR2) predict decline in renal function in both T1DM and T2DM [8,9]. However, it is not known if TNF-α receptors are directly linked to pathogenetic mechanisms in DKD.

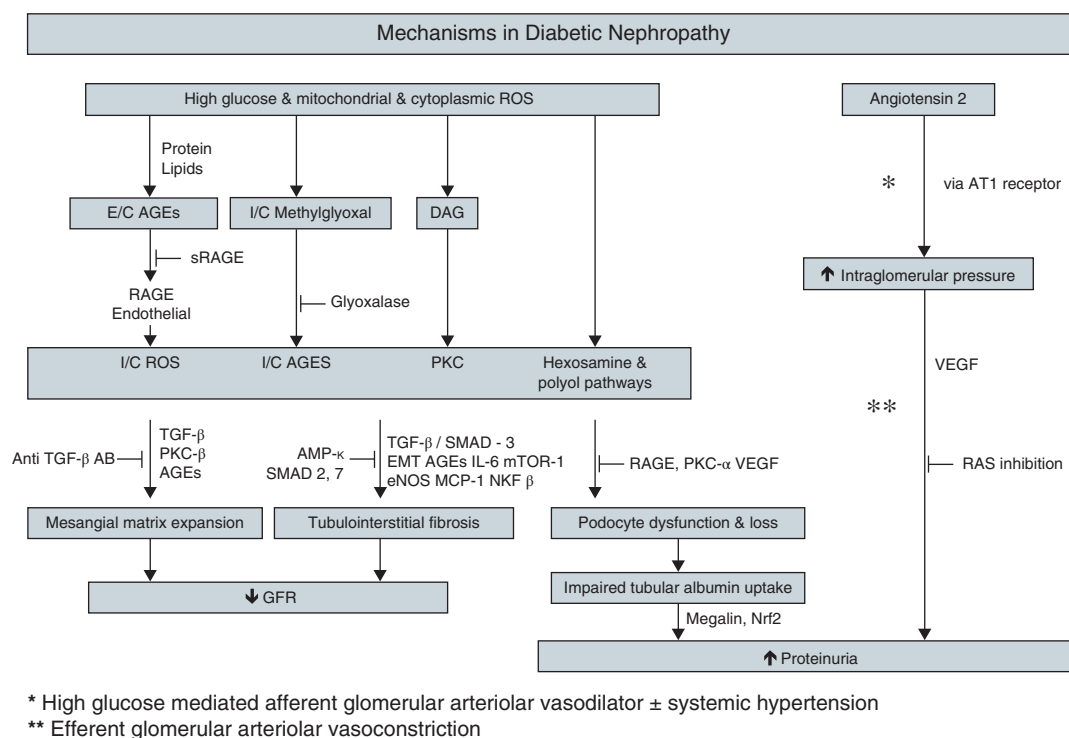
The high intra-individual variation of albumin excretion rate (AER) in diabetes and the finding of advanced renal structural changes in renal biopsies performed in subjects with minimal increases in AER suggest a need for new approaches to the detection of DN at an early stage. One such approach is proteomics, a method that allows detection of not only intact albumin, but also over 60 albumin fragmentation products. Cross-sectional studies have identified polypeptide patterns which have differentiated patients with or without DN using capillary electrophoresis coupled with mass spectroscopy (CEMS). A recent longitudinal study has shown that early DKD can be detected


Figure 62.1 Mechanisms in diabetic kidney disease (DKD). This diagram summarizes postulated contributions of oxidative stress, growth factors, inflammation, AGEs and intraglomerular pressure to the development and progression of DKD. AB, antibody; AGEs, advanced glycation end-products; AMP-K, AMP activated kinase; AT1, angiotensin 2 type 1 (receptor); DAG, diacylglycerol; E/C, extra cellular; EMT, epithelial mesenchymal transformation (induced by AGEs via RAGE); eNOS, endothelial nitric oxide synthase; I/C, intra cellular; IL-6, interleukin 6; MCP-1, monocyte chemotactic protein-1; mTOR-1, mechanistic target of rapamycin; NFκβ, nuclear factor Kappa β; PKC, protein kinase C (alpha or beta); RAGE, receptor for AGEs; sRAGE, soluble (circulating) RAGE; RAS, renin-angiotensin system inhibitors (RAS inhibitors do not prevent nephropathy but do delay the progression of overt nephropathy); ROS, reactive oxygen species; TGF-β, transforming growth factor beta; SMAD, TGF-β regulated transcription factor; VEGF, vascular endothelial growth factor.

by CEMS before the development of microalbuminuria [10]. It is not yet clear whether a CEMS pattern, attributed largely to collagen fragments, or whether novel biomarkers, identified by CHIP (chromatin immunoprecipitation) technology, will be the most appropriate path towards earlier diagnosis of DKD.

Natural history of DKD

Type 1 diabetes

At diagnosis of T1DM, there are transient increases in GFR, AER, and kidney size, which return to normal levels in most patients over several months [11]. However, GFR remains high in about one third of patients. This state of prolonged hyperfiltration has been associated with later progression to nephropathy in some studies but this has not been confirmed by others. The pathogenesis and significance of hyperfiltration are discussed in a separate section in this chapter.

In patients who progress to ESRD, microalbuminuria usually develops within 5–10 years of the diagnosis of diabetes. Factors that have been associated with the development of microalbuminuria include (nonmodifiable) duration of diabetes, family history of DKD, male sex, ethnicity, (modifiable) poor glycemic control, increased blood pressure (BP), presence of retinopathy, and smoking. Thus, both metabolic and hemodynamic factors contribute to the development DKD: in early DKD, glycemic control plays the major role [12], while in later stages, BP is the most important determinant of the rate of decline of GFR [13]. With the development of overt DN (macroalbuminuria), the rate of decline in GFR rises to around $10–12\,mL\,min^{-1}$ per year, which intensive BP control can reduce to around $4\,mL^{-1}\,min^{-1}$ per year in some but not all subjects [14].

The cumulative incidence of overt DN after 20 years duration of T1DM has fallen in some studies, from 25% in subjects diagnosed between 1953–1962 to 15% in later studies. However, a recent analysis of incidence of ESRD in T1DM by decade of diagnosis has demonstrated no difference in renal outcomes over the preceding three decades.

Type 2 diabetes

The development of DKD in T2DM shows both similarities and differences to that in T1DM. An important difference is that microalbuminuria and raised BP often precede the diagnosis of nephropathy in T2DM, or indeed T2DM itself.

Treatment of hypertension with renin-angiotensin system (RAS) inhibitors may therefore lower AER and create a state of tonic suppression of AER in the normoalbuminuric range, in which the development of microalbuminuria would only be revealed by interruption of antihypertensive therapy.

Another difference in T2DM is that ethnicity exerts a major effect on the prevalence of DKD. Compared to European subjects, there is a higher prevalence of microalbuminuria in Asians, African Americans, Maori and Pacific Islanders, and Indigenous Australians. This is also reflected in a higher prevalence of overt nephropathy and ESRD. For instance, prevalence of ESRD is 5–10-fold higher in Indigenous Australians than in white European subjects with T2DM.

As shown in the UKPDS, at each step in the progression of AER from normo- to micro- to macroalbuminuria in T2DM, the rate of stepwise increase in AER category (2–4% of patients per year) is matched by a similar increase in risk of fatal cardiovascular events. This situation of competing risks raises the possibility that aggressive use of statin therapy since the early 1990s has decreased cardiovascular deaths, and in doing so may have allowed more people with overt DN to progress to ESRD. This, coupled with progressive increases in incidence of T2DM, may have masked a decrease in the rate of progression of DKD in T2DM following the introduction of multifactorial intervention, as first shown in the Steno-2 Study [15].

A summary of the prevalence, main clinical features, and renal structural changes in DKD is shown in Table 62.3.

Predictive value of albuminuria below the microalbuminuric range

It is important to appreciate that the lower limit of microalbuminuria (AER 20 µg min^{-1}, 30 mg per 24 hours, or ACR 2.5 mg mmol^{-1} in men and 3.5 mg mmol^{-1} in women) was based on three retrospective studies in patients with T1DM in the early 1980s. In healthy young adults, the mean AER is 5 µg min^{-1} and rarely exceeds 15 µg min^{-1}. In elderly, nondiabetic subjects small increases in AER, short of microalbuminuria, are associated with macrovascular disease. In young subjects with T1DM, small increases in AER (10–20 µg min^{-1}) predict future development of microalbuminuria, whereas in older subjects with T2DM, borderline increases in AER predict either renal or cardiovascular outcomes or both [16]. Recent data in young patients with T2DM and features of the metabolic syndrome also suggest that increases in AER predict cardiovascular as well as renal outcomes to a greater degree than in patients with T1DM of similar age.

Hyperfiltration

Pathophysiology
Hyperfiltration (HF) has been postulated as a maladaptive response to glomerular hemodynamic disturbances early in the course of DKD [17]. At a glomerular level, it is caused by

Table 62.3 Comparison of nephropathy in T1DM and T2DM

	T1DM	T2DM	Comments
% Developing DN Caucasian Non-Caucasian	 20–30% 20–30%	 20–30% 30–60%	DN develops faster in obese adolescents than in older patients with T2DM.
Proportion of total ESRD attributable to diabetes	5–10%	20–40%	Over 90% of diabetic patients with ESRD have T2DM. Ethnicity is major determinant of ESRD in T2DM, with incident ESRD due to diabetes varying from 15–30% in Europe to 60% in Mexico.
Decrease in GFR according to AER status (mL min^{-1} per 1.73m^2 per year)	Normo 0–2 Micro 1–4 Macro 3–12	1–4 2–5 3–12	Average annual GFR decline in nondiabetic subjects aged >40 years is 1.0 mL min^{-1} per 1.73m^2. About one in four subjects with diabetes develop normoalbuminuric renal insufficiency (GFR <60 mL min^{-1} per 1.73m^2).
Associations with DN Insulin resistance Hypertension Dyslipidemia (⇑ TG, ⇓ HDL) Retinopathy Coronary disease	 ± follows DN onset follows DN onset precedes DN follows DN onset	 +++ usually precedes DN usually precedes DN variable often precedes DN	Insulin resistance, obesity, and metabolic syndrome contribute to DN in T2DM. Loss of nocturnal BP dip often precedes onset of microalbuminuria in T1DM.
Renal structural characteristics Glomerular (diffuse and nodular glomerulosclerosis)	 +++	 ++	Suspect nondiabetic renal disease if rapid onset of macroalbuminuria in absence of retinopathy.
Extraglomerular (interstitial fibrosis) (arteriolar hyaline change)	 ± ±	 ++ ++	Intra- and extra-renal vascular changes are prominent in older patients with T2DM.

AER, albumin excretion rate; DN, diabetic nephropathy; ESRD, end-stage renal disease (eGFR <15 mL min^{-1} per 1.73m^2); GFR, glomerular filtration rate.

increases in the glomerular capillary plasma flow rate and mean glomerular capillary hydraulic pressure, which in turn is due to changes in efferent and afferent arteriolar resistance and changes in systemic arterial pressure [18]. Increased intraglomerular pressure, as a result of greater dilatation of the afferent glomerular arteriole and/ or less constriction of the efferent arteriole, is a hallmark of early DKD. Autocrine modulation of vascular smooth muscle cell growth and proliferation in response to the augmented activity of the intrarenal renin-angiotensin system and the proliferative influence of fibroblast growth factor (FGF-23) have been documented in *in vitro* studies [19].

A major factor that has been incriminated as a cause of HF in diabetes is acute hyperglycemia, by means of activation of tubuloglomerular feedback and vasodilatation. Resolution of HF has been achieved by re-establishing a normoglycemic state [20].

Peptide and nonpeptide vasoactive agents may also be involved in the mediation of vascular changes seen in early DKD. For instance, increased nitric oxide synthesis has been associated with HF. However, it is not clear if the changes in nitric oxide production play a causal role in the pathogenesis of glomerular HF or whether they are secondary to increased renal blood flow.

HF at a renal level is also associated with a number of clinical conditions other than diabetes, such as systemic hypertension, obesity/metabolic syndrome. HF at a glomerular level occurs with congenital or acquired reduction in renal mass. Enhanced systemic production of renin-angiotensin has been recognized as a factor causing exaggeration of the pathologic effects of the intra-renal changes described earlier. Pharmacologic agents blocking the action of the renin-angiotensin system are well proven to reduce glomerular HF [21]. High dietary sodium intake and increased proximal tubular sodium resorption, as part of a tubuloglomerular feedback mechanism has also been proposed as a mediator of HF.

Clinical studies

Glomerular HF is a well-characterized phenomenon seen in approximately 24–30% of patients with early T1DM [22]. With time, glomerular filtration falls gradually in parallel with increasing albuminuria, which may eventually lead to progressive renal failure (Figure 62.2). There is no universally accepted definition for HF, but it is generally defined as a GFR of >120–135 mL min^{-1} per 1.73m^2, dependent upon the GFR methodology and the study population. While over the past four decades a number of cross-sectional and longitudinal studies have examined the prevalence of HF in diabetes, the causative or predictive role of HF in the pathogenesis of microalbuminuria or renal impairment remains largely uncertain.

A recent meta-analysis of 780 subjects with T1DM concluded that glomerular HF increased the risk of albuminuria and progression of DKD. The relative risk of progressive albuminuria was 2.71 in those with HF versus normal GFR at baseline. HF was associated with higher HbA1c in this study. By contrast, a previous study of children with T1DM, which
Figure 62.2 Clinical patterns of DKD. A: normo-hypofiltration; B: normo-hyper-normo-hypofiltration; C: normo-hyper-normofiltration; D: persistent normo-filtration.

also demonstrated a correlation of HF with microalbuminuria, failed to demonstrate an association with metabolic control. However, the concept of HF being a predictor of microalbuminuria in T1DM is not a universal finding. A case-controlled prospective study of 10 years of follow-up of 50 subjects [23] and a more recent single-center study of 15-year follow-up of 426 subjects with T1DM [24] are examples of studies that failed to demonstrate an association between glomerular HF and subsequent renal disease defined in terms of development of micro- or macroalbuminuria.

The pathogenetic role of glomerular HF is even less clear in T2DM, due to a paucity of long-term studies. The prevalence of HF is high among patients with T2DM in certain ethnic groups, such as the Pima Indians. Most studies of HF in T2DM subjects conclude that it is mainly a phenomenon in younger subjects. However, this may be related to the fact that HF is "masked" in older subjects due to the age-related decline in renal function. The prevalence of HF in T2DM has been found to increase from 7.4% to 16.6% after adjusting for the expected age-related decline in GFR [25].

In longitudinal studies, HF in T2DM has been associated with a greater rate of decline in GFR compared to T2DM subjects with normal GFR and nondiabetic controls over a 6-year period but again, this finding is controversial. A recent study of 600 hypertensive T2DM patients with normo- or microalbuminuria, 90 with HF at baseline, showed a faster decline in renal function and progression of albuminuric status over a mean follow-up period of 4 years in patients with persistent HF versus those with normal GFR at baseline and those who had their HF at baseline ameliorated by intensive BP and metabolic control [26]. Conversely, a recent pooled analysis of hyperfiltration studies in T1DM did not show a relationship between HF and increases in AER [27].

In summary, the role of HF as a causative factor in renal disease progression is still unclear and warrants further prospective longer term studies. Whether reversal of HF protects against the risk of development of albuminuria and renal impairment is also worth investigating.

Progression of DKD to ESRD

Over the past 30 years, a gradual increase in the prevalence of diabetes-related ESRD has been observed, with DKD now accounting for 30–50% of ESRD cases worldwide. Although the absolute number of subjects reaching ESRD continues to increase year by year, an age-specific analysis of ESRD due to diabetes in the United States from 1990–2006 showed that ESRD incidence per 100,000 of the known diabetic population has decreased since 2000 [28]. The incidence of ESRD in T1DM is also declining, based on studies from the USA and Finland. According to the US Renal Data System, in people aged <45 years, the incidence of diabetes-related ESRD decreased by 4.3% per year from 1999 to 2006.

It is unclear to what extent this decrease in ESRD incidence reflects better treatment of early DKD (numerator), including aggressive treatment of glycemia, hypertension, and dyslipidemia, as opposed to a higher rate of diagnosis of T2DM during the same interval (denominator). By contrast, in urbanized parts of Asia as well as in socioeconomically deprived parts of the world, the incidence of ESRD due to diabetes continues to increase [29].

Alteration of the rate of progression of DKD to ESRD requires early and intensive management of several risk factors. The most important of these is control of BP, in association with control of glycemia, dyslipidemia, smoking cessation, and avoidance of acute kidney injury associated with dehydration or exposure to radiocontrast agents. In hypertensive patients with T2DM and microalbuminuria this so-called multifactorial intervention nearly halved total mortality and ESRD in the Steno-2 Study [15].

While assessing incidence rates of ESRD, it is important to consider the competing risks of renal and cardiovascular endpoints in patients with early and late DN. A meta-analysis of all-cause mortality in patients with CKD (including DKD) showed that two parameters of renal involvement—albuminuria $\geq 1.1\,\mathrm{mg\,mmol^{-1}}$ and/or renal impairment with eGFR $<60\,\mathrm{mL\,min^{-1}}$ per $1.73\mathrm{m^2}$—predicted all-cause and cardiovascular mortality. This confirms the data from the UKPDS showing a similar risk of progression though the stages of albuminuria as cardiovascular death. It follows that any intervention which decreases cardiovascular deaths, such as statin therapy, will paradoxically increase numbers of subjects who are at risk of progressing to ESRD.

Gene variants in DKD

Ethnic and familial variability in the risk of CKD in diabetes raises the possibility that genetic factors impact upon the role of the three dominant clinical risk factors for DKD: duration of diabetes, glycemic control, and BP control. However, despite a large number of candidate genes being proposed for predicting DKD, the contribution of individual gene variants to the risk of DKD has achieved relatively modest odds ratios of 1.05–1.5 [30]. Furthermore, in contrast to genetic studies of nondiabetic CKD in the African-American population, findings of genetic variants conferring increased susceptibility have varied in studies of DKD. This inconsistency of results may be explained by inadequate sample size, varying ethnicity of participants, and differences in the duration of diabetes in the DKD group compared with controls.

Another variable complicating the interpretation of genetic studies is the phenotype of DKD. In early DKD, the development of proteinuria on the one hand, and the onset of a decline in GFR on the other, may occur at different rates [31] and may be influenced by different genetic factors [32]. Hence, studies in which the definition of DKD is according to proteinuric status will produce different results from studies where DKD is defined according to GFR trajectory or attained GFR.

A recent meta-analysis of genetic data from 3162 case subjects and 3845 controls from three studies of patients with T1DM and DKD, defined by ESRD, failed to replicate most of the previously reported genetic associations for DKD [33]. This research design targeted specific genes and therefore avoided statistical power issues in previous studies. Larger and more comprehensive studies are therefore needed, firstly to allow prediction of DKD at the time of diagnosis of diabetes, and secondly to facilitate the development of new approaches to therapy of early DKD before it becomes irreversible.

In summary, linkage and association studies in DKD have identified several chromosomal regions and candidate genes that explain a relatively small fraction of the total genetic risk associated with DKD. So far, this fraction does not compare with the advances made in understanding the genetic basis of nondiabetic renal disease in African Americans.

A novel area of gene related research involves the quantification of circulating and urinary micro RNAs. Micro RNAs are small, noncoding transcripts which influence posttranscriptional degradation of messenger RNA [34]. Circulating micro RNAs are disease biomarkers which have potential for the detection and monitoring of DKD.

Histologic changes of DN

Glomerular changes

Glomerular structure is normal in patients with T1DM at the time of diagnosis [35], indicating that hyperglycemia is necessary for the development of DKD. However, the key changes of DN, glomerular basement membrane thickening and mesangial expansion, may be evident within 2 and 5 years, respectively, of T1DM diagnosis. Diffuse and nodular mesangial expansion is an important marker of functional decline in DN. Studies in T1DM have shown a strong inverse correlation between mesangial volume fraction and GFR, probably because the expanding mesangium causes a reduction in the filtration surface area of contiguous glomerular capillaries [36]. While it is generally

accepted that the mesangial expansion and thickening of the glomerular basement membrane characteristic of DN correlates with the degree of proteinuria, this has not been a universal finding, with background RAS inhibition therapy likely playing a confounding role. Of note, the glomerular changes of DN can be reversed when assessed 10 years (but not 5 years) after pancreas transplantation.

Hyaline changes can involve both the afferent and efferent glomerular arterioles. The replacement of glomerular arteriolar smooth muscle cells by hyaline material is associated with the extent of global glomerulosclerosis, suggesting that glomerulosclerosis in DN may derive in part from vascular pathology.

Tubulointerstitial changes

Early in the natural history of DKD, the changes of tubulointerstitial disease are subtle and may be overlooked [37]. However, DKD of long duration is associated with prominent tubulointerstitial pathology, including interstitial fibrosis, tubular atrophy, and mononuclear cell infiltration. The process is related to vascular changes and may be secondary to chronic ischemia. In contrast to patients with T1DM, renal biopsies in patients with T2DM and low degrees of proteinuria may show atubular glomeruli and atrophic tubules, collectively termed glomerulotubular dysjunction. The presence of glomerulotubular dysjunction in DKD may hasten the decline in GFR.

DKD in the absence of elevated AER

An increase in AER classically heralds incipient DKD. However, studies in normotensive patients with T1DM who also have a normal AER and GFR have demonstrated mesangial volume fractions ranging from normal to levels bordering on those usually associated with overt DN. Thus, it now appears that a normal AER does not preclude the existence of structural abnormalities, while the converse also appears true.

The structural basis of DKD without elevations in AER in T2DM remains to be elucidated. However, in patients with T2DM, microalbuminuria and preserved GFR (mean $101 \, \text{mL} \, \text{min}^{-1}$ per 1.73m^2) findings on renal biopsy are heterogeneous. They include normal or near-normal glomerular and tubulo-interstitual appearance, typical DN with emphasis on glomerular mesangial expansion and basement membrane thickening, or an atypical histologic picture comprising disproportionately severe interstitial/tubular/vascular damage and relatively preserved glomeruli.

Non-DKD in people with diabetes

In patients with T1DM and overt renal disease, the prevalence of nondiabetic CKD is uncommon (<5%). In T2DM, by contrast, up to 25% of patients with CKD have been reported to have nondiabetic CKD. However, this may reflect a clinical bias in the selection of patients for renal biopsy.

In summary, the histologic changes underlying renal dysfunction are much more heterogeneous in patients with T2DM than in patients with T1DM, although patients with T2DM and diabetic retinopathy have an increased likelihood of developing renal pathology similar to that in T1DM. The relationships between the natural history of CKD and the contributions of global glomerulosclerosis, arteriolar hyalinosis, and chronic tubulo-interstitial injury remain inadequately described in people with T2DM.

Prevention, screening, and monitoring of DKD

DKD does not occur in the absence of hyperglycemia and, hence, preventing the transition from normal glucose tolerance to diabetes is the ultimate means of preventing the development of this complication. Studies investigating the prevention of DKD have mainly focused on the development of microalbuminuria. However, currently attention is also being placed on the concept of trying to prevent an early decline in GFR (before reaching $60 \, \text{mL} \, \text{min}^{-1}$ per 1.73m^2), although data are sparse on how best to achieve this. In T2DM, very good BP control appears to be an important factor in preventing the development of microalbuminuria. Recent studies have also investigated the role of RAS blocking agents in preventing the development of microalbuminuria.

In patients with T2DM and hypertension, angiotensin converting enzyme (ACE) inhibitors attenuate the progression from normoalbuminuria to microalbuminuria. However, in normotensive patients with T1DM, the angiotensin II receptor blocker (ARB) losartan, or the ACE inhibitor enalapril, did not reduce the 5-year cumulative incidence of microalbuminuria compared to placebo treatment. Furthermore, the use of RAS blocking agents did not slow the development of early renal structural characteristics of DN. Possibly, there has to be sufficient intrarenal RAS activation, for example in hypertensive patients or those with late nephropathy, before the benefits of RAS inhibition become apparent.

Screening patients at risk for DKD usually involves testing for the presence of persistent microalbuminuria and estimating GFR. Laboratory-based screening for microalbuminuria can be achieved in a number of ways:

- a 24-hour urine collection for the estimation of AER, accepted as the gold standard with the added advantage of allowing for the estimation of creatinine clearance;
- a spot urine collection for the estimation of the albumin to creatinine ratio (ACR);
- a timed 4-hour or overnight collection for the estimation of AER.

Alternatively, screening for microalbuminuria can be performed on spot or early morning urine samples using special

reagent strips. The reference ranges of albuminuria for AER and ACR 24-hour urine collections and spot urine samples for ACR are described in Table 62.1. At least two out of three consecutive estimations of albuminuria should fall into the microalbuminuric range before a diagnosis of persistent microalbuminuria is made. Increases in albuminuria into the microalbuminuric range may occur transiently with exercise, urinary tract infection, uncontrolled hyperglycemia, and cardiac failure. In patients with T1DM, it is recommended that annual screening for microalbuminuria should commence approximately 5 years after diagnosis, as the development of diabetic complications is rare before this time. In contrast, given that approximately 20% of newly diagnosed subjects with T2DM have microalbuminuria, it is recommended that all subjects with T2DM are screened from the time of diagnosis.

Current gold standard methods for determining GFR, employing the clearance of radioisotopes or nonradiolabeled markers, are time consuming and expensive, and thus not easily adaptable to routine clinical practice. Therefore, creatinine has been used as an endogenous marker of GFR for many decades. Unfortunately, the influence of nonrenal factors on serum creatinine concentrations, including age, gender, ethnicity, muscle mass, and dietary protein intake, limit its usefulness as a marker of GFR. To overcome the limitations of using creatinine alone, there are now equations to estimate GFR based on serum creatinine as well as age, sex, and race, namely, the Modification of Diet in Renal Disease (MDRD) equation [38].

In patients with GFR in the normal or hyperfiltration range, GFR is grossly underestimated by the MDRD formula by approximately $10-40\,\text{mL}\,\text{min}^{-1}$ per 1.73m^2. To overcome the limitations of the MDRD equation a new creatinine-based formula, based on the original variables used in the MDRD formula, has been devised to improve estimation of GFR in individuals with a GFR $>60\,\text{mL}\,\text{min}^{-1}$ per 1.73m^2, that is, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation [39]. However, the CKD-EPI equation has yet to be rigorously tested in subjects with diabetes with high-normal GFRs. In contrast, recent studies have suggested that estimates of GFR based on serum cystatin C concentrations provide a simple and accurate method for detecting and monitoring an early decline in renal function. Although cystatin C is well established as a research tool, it has yet to make the transition to use in routine clinical practice.

Once the urinary albumin threshold for microalbuminuria has been reached, AER or ACR should be measured every 3–6 months. Measurement of serum creatinine to allow for automatic reporting of an eGFR should also be made every 3–6 months. However, as discussed earlier, existing methods for estimating GFR are only robust below a threshold of $60\,\text{mL}\,\text{min}^{-1}$ per 1.73m^2. The implication is that approximately one half of total kidney filtration rate can be lost before it is possible to accurately detect a decline in renal function using current clinical parameters. Nevertheless, serial measurements of eGFR between $90-60\,\text{mL}\,\text{min}^{-1}$ per 1.73m^2 are useful for detecting trends in GFR trajectory which may occur without changes in AER.

Management of DKD

Glucose control (Table 62.4(a))

Glycemia is the major determinant for the onset of DKD. Both the DCCT in T1DM and the UKPDS in T2DM demonstrated the strong relationship between glycemic control and the risk of the development of diabetic microvascular complications, without a clear-cut threshold of HbA1c concentration. However, a recent sophisticated observational analysis from the ADVANCE study involving subjects with T2DM suggested that within the range of HbA1c studied (5.5–10.5%), below an HbA1c threshold of 6.5% there was no significant increase in the risks of retinopathy or late renal complications including macroalbuminuria, doubling of serum creatinine, the need for renal-replacement therapy, or death due to CKD [40].

Table 62.4(a) Effects of interventions on renal outcomes in diabetes

| eGFR (mL min⁻¹ per 1.73m²) | Glycemic control: | |
	T1DM	T2DM
≥60	Attained A1c 7.2% over 6.5 yrs (DCCT) (i) reduces incident micro- and macro- AER (ii) Reduces GFR decline to <60 from 5.5% (standard) to 2.0% (intensified) over 22 yrs DeBoer [63] (DCCT/EDIC)	(i) Attained A1c 7.0% over 10 yrs reduces incident micro- and macro- AER (UKPDS 33) [64]. (ii) Attained A1c 6–7%: reduces incident micro- AER, with no effect on GFR decline (ADVANCE), but may reduce progression to ESRD in macro- AER (NNT 41) [42]. (iii) Combined glucose and BP control reduces diabetes-related events more than either intervention alone (UKPDS 75) [65].

In the DCCT, the development of microalbuminuria in T1DM patients was reduced by 34% and macroalbuminuria by 56% through tight glycemic control (HbA1c <7.0%). An interventional analysis of the UKPDS in T2DM patients demonstrated that reducing mean HbA1c concentrations from 7.9 to 7.0% was associated with an absolute risk reduction for the development of overt nephropathy of 11% over 12 years, and a relative risk reduction of 30% for the transition from normo- to microalbuminuria.

More recently, results from the DCCT/EDIC research group have shown that in T1DM, the long-term risk for the development of an impaired GFR (<60 mL min^{-1} per 1.73m^2) was significantly lower for people who were initially treated to achieve tight glycemic control. In T2DM patients, a meta-analysis of intensive glucose control studies has shown that compared to conventional control, intensive glycemic control reduces the risk of developing microalbuminuria (risk ratio 0.86; 95% CI 0.76–0.96) and macroalbuminuria (risk ratio 0.74; 95% CI 0.65–0.85). However, the risk for the development of ESRD was not significantly different compared with conventional glucose control. This result was possibly related to the relatively low incidence of ESRD (<1.5%) compared with that of microalbuminuria (23%) and macroalbuminuria (5%) [41].

By contrast, a recent analysis of the ADVANCE study has shown that intensive glucose control does reduce the incidence of ESRD [42]. One ESRD event was prevented when 41 participants with macroalbuminuria at baseline were treated intensively over 5 years.

In summary, the HbA1c threshold for the development of DKD remains to be clearly defined but is likely to be around 6.5%, the same as the currently accepted cut-off for the diagnosis of diabetes. Recent evidence has shown that intensive glucose control not only reduces the incidence of micro- and macroalbuminuria but may also reduce the incidence of ESRD to a lesser degree. In this setting, there is increasing clinical awareness that appropriate glycemic targets to prevent diabetes-related complications need to be individualized for each patient.

Blood pressure (BP) control (Table 62.4(b))

In patients with T1DM, elevations in BP are usually due to underlying DKD as, typically, BP only begins to rise around the time of transition from micro- to macroalbuminuria. In contrast, hypertension may be present in approximately one third of patients with T2DM at the time of diagnosis. In this setting, the etiology of hypertension is most likely multifactorial and represents a component of the metabolic syndrome. Regardless of the sequence or underlying causes of hypertension in T1DM and T2DM, many studies have demonstrated that high BP accelerates the progression of DKD and that aggressive BP lowering retards the deterioration in renal function.

The recommended BP target for people with diabetes is 140/80 mmHg [43]. If persistent proteinuria is present, then a more stringent target of less than 130/75 mmHg has been recommended, although this is not achievable in most elderly subjects with T2DM. As discussed later, antihypertensive

Table 62.4(b) Effects of interventions on renal outcomes in diabetes

| eGFR (mL min^{-1} per 1.73m^2) | Blood pressure control: | |
	T1DM	T2DM
≥60	NORMO: In normotensive subjects: Early blockade of RAS slows progression of retinopathy but not nephropathy (RASS) [66]. MICRO: ACEi reduces AER with minimal change in GFR.	NORMO: (i) ACEi, but not non-DHP-CCB, reduces incident MICRO-AER (BENEDICT) [67]. (ii) Attained SBP <130 mmHg in subjects with high CV risk is associated with greater decrease in GFR (ACCORD) [68]. MICRO: ARB reduces AER with minimal change in GFR. Initial decrease in AER predicts long-term GFR outcomes by post hoc but not ITT analysis.
<60	MACRO: ACEi-based therapy reduces doubling of serum creatinine or development of ESRD by 30% (LEWIS) [47].	MACRO: (i) ARB-based therapy reduces doubling of serum creatinine or development of ESRD by 16–30% (IDNT) [69], (RENAAL) [52]. (ii) Early AER decrease predicts long-term GFR outcomes by ITT analysis. (iii) ARB delays ESRD by ~1 yr (IDNT) [69]. (iv) In USA, since 2000, incident ESRD (>90% T2DM) has leveled off at 155 per million per year.

ITT, intention to treat.

medications that interrupt the RAS appear to have renal protective effects over and above those expected from BP lowering effects alone. However, this superior effect is progressively reduced as blood pressure declines. Achieving BP goals commonly requires the combination of three to four different antihypertensive medications, particularly in subjects with T2DM. People with diabetes, especially those with DKD, are also at higher risk of CV disease; therefore, achieving BP targets offers both renal and CV disease protection. It is recommended that initial antihypertensive therapy be commenced with an agent that inhibits the RAS. While diuretics and dihydropyridine calcium channel blockers are useful additional agents, the ACCOMPLISH [44] trial suggests that adding a calcium channel blocker to an ACE inhibitor offers advantages over the addition of a thiazide diuretic. The choice of antihypertensive agents will depend to some extent on the subject's clinical circumstances, as these may preclude certain drug combinations (e.g. the combination of β-blockers and nondihydropyridine calcium channel blockers), or dictate the early introduction of specific antihypertensive agents.

Although observational studies suggest a continuous relationship between BP levels and renal and CV events in people with diabetes, very few interventional studies have achieved BP levels below 130/80 mmHg. The results of both the ACCORD-BP [45] trial and INternational VErapamil SR Trandolapril Study (INVEST) [46], which have attained BP levels of <130/80 mmHg, suggest that lowering BP below these levels has little impact on reducing clinical events below those seen with moderate BP control.

Ambulatory blood pressure monitoring (ABPM) provides measurements of several variables that are of potential value in estimating the risk of clinical outcomes in diabetes. These include an estimate of "true" BP levels and the identification of the "white-coat" effect as well as the measurement of the diurnal rhythm of BP that allows patients to be classified into nocturnal "dippers" and "nondippers" (a difference between mean daytime and nocturnal BP of <10%). Nondipping can be treated by administrating BP-lowering drugs in the evening. Another use of ABPM is the recording of random variability of BP and ambulatory heart rate as measures of autonomic function. Importantly, it should be noted that the clinical trial information presented earlier, especially relating to BP targets, has been based on clinical BP recordings.

Renin-angiotensin system (RAS) inhibition (Table 62.4(b))

In patients with diabetes, activation of the intrarenal RAS produces hemodynamic and nonhemodynamic effects that contribute to the development and progression of DKD. There is now good evidence suggesting that interrupting the RAS with an ACE inhibitor or an ARB results in renal and CV protective effects over and above those observed by BP lowering alone. In a landmark trial, Lewis and colleagues [47] demonstrated that the ACE inhibitor captopril reduced the risk of achieving the combined endpoint of death, dialysis, and transplantation compared to BP control alone achieved with non-RAS blocking agents in subjects with T1DM and advanced nephropathy (macroalbuminuria). In another important study, captopril significantly reduced the progression from micro- to macroalbuminuria and prevented an increase in AER in patients with T1DM [48]. A subsequent systematic review of the effects of ACE inhibition in patients traditionally classified as normotensive, who also had microalbuminuria, has been performed (ACE Inhibitors Trialist Group 2001). It concluded that ACE inhibition use significantly reduced the progression to macroalbuminuria and increased the chances of remission to normoalbuminuria. However, the Renin-Angiotensin System Study (RASS) [49], using angiotensin receptor blockade or ACE inhibition in normotensive, normoalbuminuric patients with T1DM did not show any effects on the rate of progression of AER from normo- to microalbuminuria [50].

For patients with T2DM and microalbuminuria, the use of either ACE inhibitors or ARBs has been shown to reduce urinary albumin excretion and CV events, but has not been shown to affect renal function decline [53]. By contrast in patients with T2DM, hypertension, and macroalbuminuria, the use of an ARB, superimposed on background antihypertensive therapy, slows the progression to ESRD compared to placebo (IDNT [51] and RENAAL [52]) and the decrease in albumin excretion rate predicts the subsequent rate of decline of renal function [53].

Dual blockade of the RAS with an ACE inhibitor and ARB in subjects with T2DM and microalbuminuria has been demonstrated to be more effective in reducing BP and decreasing albuminuria than either agent as monotherapy. However, outcome studies have highlighted an increase in adverse outcomes with this approach (ONTARGET study) [54]. The combination of an ACE inhibitor and ARB is therefore generally not advised but can still be considered as a therapeutic option in patients with progressive albuminuria in the macroalbuminuric range or in patients with refractory hypertension (>160/100 mmHg).

Dyslipidemia (Table 62.4(c))

The role of dyslipidemia in the initiation and progression of DKD remains poorly defined. Several cross-sectional and prospective studies have shown associations between dyslipoproteinemia, specifically elevation in apoB-100 containing lipoproteins and low HDL-cholesterol, and albuminuria in subjects with diabetes.

In a post hoc analysis from the ADVANCE study in T2DM, low baseline HDL concentrations were associated with a significantly higher risk for the development of new microalbuminuria and macroalbuminuria.

Studies involving the FinnDiane cohort of T1DM patients have suggested that higher triglyceride concentrations are associated with progressive albuminuria, whereas total cholesterol concentration was the only lipid parameter associated with progression to ESRD in an adjusted Cox regression model that

Table 62.4(c) Effects of interventions on renal outcomes in diabetes

	Lipid control:	
eGFR (mL min^{-1} per 1.73m^2)	T1DM	T2DM
≥60	No large studies have assessed statin effects on AER or GFR in T1DM	(Primary prevention): (i) Compared with placebo, fenofibrate reduces AER and slows annual eGFR decline from 6.9 to 1.9 mL min^{-1} per 1.73m^2 [57]. (ii) Statins reduce CV events but do not affect DN [70]. (iii) Fenofibrate reduces CV events only in subgroup with ⇑ TG/ ⇓ HDL [71].

included HbA1c, sex, smoking, blood pressure, BMI, duration of diabetes, and eGFR [55].

Randomized controlled trials have suggested that statins may preserve renal function and that a greater degree of renal preservation is seen for patients treated with higher doses of statins who also achieved the greatest reductions in LDL-cholesterol and triglyceride [56]. However, in the Atorvastatin Study for Prevention of Coronary Artery Disease Endpoints in Non-Insulin Dependent Diabetes Mellitus (CARDS) trial, treatment with atorvastatin was not associated with progression or regression of albuminuria.

In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) [57] and ACCORD studies, the use of fenofibrate was shown to reduce albuminuria. A further analysis of the FIELD study showed that fenofibrate caused an acute but sustained plasma creatinine increase that does not reflect changes in true GFR. In the FIELD study, plasma creatinine concentrations were re-measured 8 weeks after treatment cessation. After this washout period, eGFR had fallen less ($p < 0.001$) from baseline in patients treated with fenofibrate (1.9 mL min^{-1} per 1.73m^2) than in patients on placebo treatment (6.9 mL min^{-1} per 1.73m^2). Greater preservation of eGFR with fenofibrate was observed in patients with baseline hypertriglyceridemia alone or when combined with a low HDL-cholesterol concentration. Furthermore, fenofibrate reduced urinary ACR by 24% versus 11% with placebo treatment ($p < 0.001$). There was 14% less progression and 18% more regression of albuminuria in fenofibrate compared with placebo-treated patients ($p < 0.001$). However, ESRD event frequency was similar for fenofibrate and placebo-treated patients ($n = 21$ vs. 26; $p = 0.48$). The FIELD investigators interpreted these findings to mean that use of fenofibrate is associated with a reduction in albuminuria and a slowing in eGFR decline despite initial and reversible increases in plasma creatinine [57]. The ACCORD study also showed that fenofibrate induced a reversible short-term decline in eGFR but did not confirm that fenofibrate slows long-term eGFR decline in T2DM [58].

Lifestyle factors

Obesity per se is associated with the development of a specific form of focal and segmental glomerulosclerosis, characterized by massive proteinuria. The underlying patholophysiology includes insulin resistance, hypertension, adiponectin deficiency, and hyperaldosteronism, which could all contribute to the development of proteinuria in obese people with diabetes. There is some evidence that weight loss reduces proteinuria and stabilizes progression of CKD in obese people with and without diabetes. In obese people with DKD, weight loss should be encouraged and promoted through the use of diets low in calories and saturated fats. Weight loss achieved with bariatric surgery has been associated with significant reduction in albuminuria.

Several observational studies have documented an association between smoking and DKD. In particular, smoking appears to promote the initiation of microalbuminuria and the subsequent transition to macroalbuminura. Furthermore, evidence exists to suggest that cessation of smoking retards the progression of DKD. Thus, despite a lack of definitive interventional studies for smoking, there is a strong rationale for the inclusion of smoking cessation in the management of subjects with DKD.

Other interventions

While the American Diabetes Association guidelines for the management of DKD recommend a protein intake of $0.8 \, \text{g kg}^{-1} \, \text{d}^{-1}$ in patients with overt nephropathy, the difficulty experienced by patients in following a low-protein diet long term should be recognized.

Anemia is common in patients with diabetes and has been considered a potential risk factor for the progression of DKD [59]. However, evidence has emerged from randomized controlled trials that correcting anemia with erythropoiesis-stimulating agents in subjects with DKD prior to dialysis is associated with an increased risk of serious adverse outcomes and no evidence of any beneficial effect. Therefore, treatment of anemia with erythropoiesis-stimulating agents in subjects with

diabetes and predialysis CKD is generally not recommended. Patients should still be screened for other reversible causes of anemia, such as iron deficiency and treated appropriately.

Recent studies do not support the universal use of aspirin for the prevention of CV events in patients with diabetes. However, given the increased CV risk associated with CKD it is reasonable to consider aspirin for the primary prevention of CV disease in people with DKD. Clopidogrel does not appear to be a suitable alternative antiplatelet drug for people with DKD. Newer antiplatelet drugs have become available in recent years, but their effectiveness and safety in lowering CV risk in diabetes requires further evaluation.

In general, patients with diabetes and a GFR <30 mL min^{-1} per 1.73m^2 should be referred to a nephrologist in preparation for the commencement of renal replacement therapy. Referral should also be considered for patients found to have nephrotic range proteinuria, or when the diagnosis of the underlying cause for renal impairment is uncertain.

Multifactorial interventions

The management of people with DKD involves strict attention to the common risk factors for kidney and CVD disease; namely, hyperglycemia, hypertension, dyslipidemia, and smoking. Intensive multifactorial intervention was first performed in the Steno-2 study [15] which used treatment targets of HbA1c $<6.5\%$, systolic BP <130 mmHg, diastolic BP <80 mmHg, fasting cholesterol <4.5 mmol L^{-1}, and fasting triglycerides <1.7 mmol L^{-1}. The study involved the universal use of RAS inhibitors, aspirin, the aggressive use of statins, and attention to lifestyle factors. This approach decreased the risk of developing overt proteinuria by 60% and CV events by approximately 50% in people with T2DM, hypertension, and microalbuminuria followed for 8 years. These results were achieved despite only a minority of subjects reaching the targets for glycemia and BP control. In addition, a 5-year observational study that monitored the development of complications after the completion of the interventional phase of the Steno-2 study showed that the risk of developing ESRD was significantly reduced in people assigned to the above multifactorial, target-driven management strategy compared to those who originally received conventional treatment. The effects of intensified glucose, BP and lipid interventions on renal and CV outcomes in people with diabetes are summarized in Table 62.4(a).

Novel interventions

Despite the wide use of available therapies that target the RAS, people with DKD still progress to ESRD. Current strategies based on RAS inhibition are only partially effective. This may, in part, be due to the interference of ACE inhibitors or ARBs with negative feedback mechanisms resulting in a reactive increase in plasma renin activity. Aliskiren, an oral direct renin inhibitor, was investigated in the Evaluation of Proteinuria in Diabetes (AVOID) trial and found to reduce ACR in subjects with T2DM and overt DN who were already receiving the

maximal recommended doses of an ACE inhibitor. However, a recent clinical endpoint study (The Aliskiren Trial in T2DM Using Cardio-Renal Endpoints (ALTITUDE)) was ceased due to adverse outcomes in participants randomized to the combination of aliskiren plus another RAS-blocking agent. It remains unclear whether the adverse outcomes in the aliskiren group were related to the degree of BP-lowering or to some other mechanism.

Unfortunately, the potential benefits of promising DKD interventions such as aminoguanidine, sulodexide, and bardoxolone have not come to fruition when tested in large clinical trials. Recently, paricalcitol, a vitamin D receptor activator, has been shown to reduce albuminuria in subjects with T2DM and macroalbuminuria without an increased incidence of hypercalcemia or other serious adverse events. Whether vitamin D activation treatment results in a preservation of GFR has yet to be tested in clinical trials. Other vitamins, such as vitamin B complexes, have no effect on proteinuria but have caused a significant decline in GFR compared with placebo-treated subjects. Benfotiamine also does not appear to have any effect on urinary albumin excretion in subjects with T2DM. Other agents, such as the endothelin antagonists, reduce albuminuria but currently have an unacceptable side effect profile. It is possible that even older drugs, such as allopurinol, may be shown to play an important role in ameliorating the progression of DKD in future years, with raised uric acid concentrations emerging as an important risk factor for progressive renal disease. Lastly, preclinical studies of DKD suggest that specific antifibrotic agents may provide another novel approach to slowing the progression of DKD. The antifibrotic agent, pirfenidone, has been shown to slow the rate of decline of estimated GFR over 12 months in subjects with established diabetic nephropathy [60]. However, this requires confirmation in a longer study before pirfenidone can be considered for clinical use.

[2]Uttaranchal Ayurvedic Medical College, Dehradun, India
[3]Weill Cornell Medical College, Doha, Qatar

Key points

- Diabetic neuropathy has multiple manifestations, which result in increased morbidity and mortality.
- Demyelination and axonal degeneration are the primary pathologic features of diabetic neuropathy.
- Skin biopsy has enabled early identification of small fiber pathology in diabetic neuropathy.
- Corneal confocal microscopy represents a novel, noninvasive clinical technique for the early diagnosis, assessment of progression and benefits of therapeutic intervention, making it an ideal surrogate endpoint for diabetic neuropathy.

Introduction

Detailed study of the pathology of diabetic neuropathy requires the quantification of structural alterations in nerve or nerve-containing tissue from patients with diabetes. Biopsy of the sural nerve represents the gold standard for accurate morphometric evaluation of neuropathology in patients with peripheral neuropathy. It allows the evaluation of large myelinated, and in particular small unmyelinated nerve fibers as well as blood vessels. Inherent with the focus on neurophysiologic abnormalities in diabetic neuropathy, large myelinated nerve fibers have been studied the most. Until recently very few studies have assessed small fibers, even though small fiber/autonomic dysfunction has been shown to have comparable sensitivity/specificity for detecting neuropathy [1] and they constitute 79.6% [2] to 91.4% [3] of peripheral nerve fibers. Moreover, they underlie painful diabetic neuropathy and are key to the genesis of foot ulceration via sudomotor dysfunction [4], reduced pressure-induced vasodilatation [5–7], and, of course, impaired heat and pain perception [8]. This chapter will consider the significant contribution that sural nerve biopsy studies have made to our understanding of the pathology and pathogenesis

of human diabetic neuropathy and will then also evaluate the increasing contribution of recent studies utilizing skin biopsies [9] and the novel technique of corneal confocal microscopy in evaluating human diabetic neuropathy [10–12].

Nerve biopsy

The majority of nerve biopsy studies have been undertaken in the sural nerve due to the fact that it is distal, sensory, and relatively easy to biopsy [13]. In the upper limb the posterior interosseous nerve, a sensory branch of the radial nerve, has also been biopsied and studied [14]. Morphometric evaluation has involved predominantly light and electronmicroscopy in glutaraldehyde fixed tissue, although some studies in amyloid neuropathy [15,16] and diabetic lumbosacral radiculoplexus neuropathy [17,18] have undertaken immunohistologic evaluation in paraffin sections to provide considerable insight into the pathogenesis of these conditions. Whilst sural nerve biopsy is a valuable tool for the study of diabetic neuropathy, concerns of persisting pain and numbness [19,20] from traditional whole sural nerve biopsy have led to the use of fascicular biopsy techniques [21].

Myelinated fibers

Density

A loss of myelinated fibers is the most striking feature of diabetic neuropathy and can be assessed by quantifying myelinated fiber density (MNFD) which is derived by counting the number of myelinated fibers within each fascicle and expressing the result as no. mm^2. Whilst most studies consistently demonstrate a progressive reduction in myelinated fiber density with increasing severity of neuropathy (Figure 63.1(a–d)), it is important to note that loss of myelinated fibers is not the earliest feature of diabetic neuropathy and indeed demyelination precedes a loss
---

Figure 63.1 Light microscopic images of sural nerve fascicles from a control subject (a), diabetic patient with minimal (b), moderate (c), and severe (d) neuropathy showing a progressive loss of myelinated fibers (mf) (×300). (For a color version of this figure, please see color plate section.)

of myelinated fibers [3]. Of course the loss of myelinated fibers can be extreme in type 1 diabetic patients with somatic and autonomic neuropathy, such that in a group of five patients aged 22–34 with an uncommonly severe symmetric polyneuropathy, myelinated fiber density was reduced to 20 +/− 14% of that in five control subjects [22,23]. Similarly, in diabetic patients with more advanced neuropathy and concomitant autonomic deficits the extent of myelinated fiber loss is extremely pronounced [22,24–27]. Myelinated nerve fiber loss has been related to electrophysiologic measures of neuropathic severity [28–30] and elevated vibration perception [22]. There are precise relationships between different structural components of the myelinated fibers, thus as early as 1966 Lascelles and Thomas demonstrated a linear relationship between intermodal

length and axonal diameter [31]. The seminal study which defined a relationship between structure and function involved the morphologic study of sural nerves in five patients with mild sensory involvement, four with severe, symmetrical sensory-motor polyneuropathy, and three with multiple mononeuropathy [29]. All demonstrated a loss of large and small myelinated and unmyelinated fibers and teased fiber studies showed predominant segmental remyelination. The relation between the conduction velocity and the diameter of the largest fibers indicated that approximately 20–30% of the conduction slowing was due to causes other than fiber loss [29], such as changes in internodal length [32] and, of course, demyelination which was first reported in diabetic neuropathy by Thomas and Lascelles in 1965 [33]. In a sural nerve biopsy study MNFD

was reduced compared with control biopsies ($4042 +/- 2090$ ($+/-$ SD) vs. $6800 +/- 1100$ mm^2; $p < 0.01$) and correlated significantly with sural sensory conduction velocity ($r = 0.84$; $p < 0.001$), sural action potential amplitude ($r = 0.74$; $p < 0.001$), peroneal motor conduction velocity ($r = 0.58$; $p < 0.02$), and median sensory amplitude ($r = 0.64$; $p < 0.01$) but did not correlate with any quantitative sensory test [34]. Vibration sense threshold has been positively correlated with the total number of myelinated fibers [22]. In a longitudinal (7–10-year) follow-up study of 10 subjects with T2DM and 10 subjects with IGT a baseline MNFD ($<$ or $= 4700$ fibers per mm^2) was associated with a decline in peroneal amplitude ($p < 0.02$) and conduction velocity ($p < 0.04$), as well as median nerve sensory amplitude ($p < 0.05$) and motor conduction velocity ($p < 0.04$) [35]. More recently two studies have defined progression of diabetic neuropathy as a >500 per mm^2 loss of myelinated fiber density over 12 months and performed clinical and genomic studies to demonstrate a link between hypertriglyceridemia and a range of other putative genes with the progression of neuropathy [36,37]. Such a rapid and extreme reduction in myelinated fiber density does not reflect the natural history of myelinated fiber loss, and likely delineates the rapid progressors; therefore these findings may not necessarily be applicable to all diabetic patients who develop neuropathy. Evaluation of the regenerative cluster density (Figure 63.2) has also been undertaken to attempt to understand the balance between degeneration and regeneration of myelinated fibers [23,38]. In a sural nerve biopsy study the number of regenerating fibers, identified by light microscopy, was found to decline in proportion to the reduction in total myelinated fiber density; however, the relative number of regenerating fibers was significantly greater in patients with T1 compared to T2DM [38]. However, no relationship has been found between the regenerative capacity assessed by quantifying regenerative clusters and painful symptoms of diabetic neuropathy [25]. Apart from a generalized loss of myelinated fibers, a change in the spatial distribution of nerve fiber loss, proximally [39] has been demonstrated to suggest a vascular basis for diabetic neuropathy, although another study has demonstrated comparable patchy fiber loss in a series of sural nerve biopsies from patients with diabetic neuropathy and type 1 hereditary motor and sensory neuropathy, questioning a vascular causation [40]. However, fascicular sural nerve morphometry has demonstrated significant differences between 11 T1DM patients and 17 T2DM patients with comparable duration and severity of hyperglycemia and severity of neuropathy [41]. Thus in patients with T2DM there was evidence of predominantly Wallerian degeneration with the spatial pattern of fiber loss quantified using the intrafascicular coefficient of variation demonstrating a multifocal pattern, consistent with ischemia. Pathology has also been quantified in the posterior interosseous nerve (PIN) in the forearm [14] in 26 diabetic and 20 nondiabetic patients with carpal tunnel syndrome (CTS) and 13 control subjects. PIN myelinated nerve fiber density was significantly reduced in diabetic and nondiabetic patients with

Figure 63.2 Electromicrograph showing a regenerative cluster in a sural nerve biopsy from a diabetic patient with severe neuropathy (×6000).

CTS compared to control subjects and diabetic patients had a significantly lower density than nondiabetic patients [42].

Axonal atrophy

Based on a series of experimental studies showing a reduction in the distal myelinated fiber axonal caliber in relation to the number of myelin lamellae compared to controls it has been suggested that axonal atrophy occurs in diabetic neuropathy [43] (Figure 63.3(a,b)). In a study of 15 diabetic patients with mild neuropathy and 14 control subjects, whilst the diabetic patients demonstrated a significant reduction in myelinated fiber density, there was no change in fiber and axonal area, or g-ratio, compared to control subjects [30]. A detailed electron-microscopic morphometric study of sural nerve biopsies from 8 patients without and 25 patients with diabetic neuropathy and 24 healthy subjects undertook a more detailed assessment of axonal atrophy and demonstrated that the regression lines of the natural log (In) of axonal area and index of circularity (IC) (an index that is decreased with atrophy or shrinkage) on the number of myelin lamellae and the rate of adaxonal sequestration did not differ significantly in large myelinated fibers of diabetic patients compared to controls. However, interestingly, significant differences were found in regression lines of both In axonal area and IC on the number of lamellae for small myelinated fibers and all fibers, but were

[RFU]), fibers with disproportionately large Schwann cells (cytoplasm and myelin) relative to axon caliber were exclusively found in patients with neuropathic pain, suggesting that axonal atrophy may be involved in the generation of neuropathic pain [25]. In a 12-month randomized, placebo-controlled, double-blind clinical trial, sural nerve biopsies were obtained in 10 neuropathic diabetic patients treated with the aldose reductase inhibitor sorbinil and in 6 patients treated with placebo at baseline and follow-up. Axonal atrophy was assessed using three independent morphometric techniques and exhibited a significant recovery in the sorbinil-treated patients [45]. Therefore larger studies are required to confirm or refute the occurrence of axonal atrophy as its occurrence, or lack of, may have significant connotations towards our understanding the mechanistic basis and perhaps treatment of diabetic neuropathy, especially as recent findings in other neuropathies have begun to unravel the molecular basis for this change [46,47].

Axoglial dysjunction

In 12 diabetic patients with minimal neuropathy, whilst myelinated fiber density, fiber and axonal area, and g-ratio were normal, teased fiber studies showed significant paranodal abnormalities, segmental demyelination and remyelination without axonal degeneration [3]. Therefore paranodal abnormalities, in the form of "axo-glial dysjunction" possibly suggesting an early Schwann cell abnormality, may be important in the genesis of diabetic neuropathy. Indeed this term was first coined in 1986 when morphometric analysis in long-term spontaneously diabetic BB-Wistar rats demonstrated "a striking disappearance of paranodal axo-glial junctional complexes that was not corrected by insulin replacement" [48]. It was hypothesized that loss of these junctional complexes, may allow lateral migration of axolemmal Na channels away from nodes of Ranvier, leading to diminished nodal Na permeability and resultant nodal conduction delay. Morphometric assessment of this abnormality is of course very much dependent on adequate fixation and therefore not reliable. The authors who originally described this abnormality have demonstrated a significant improvement in axo-glial dysjunction after a 12-month randomized, placebo-controlled, double-blind clinical trial of the aldose reductase inhibitor sorbinil. However, two independent studies of sural nerve biopsies from diabetic patients have failed to confirm the presence of axo-glial dysjunction [49,50] and therefore the validity of axoglial dysjunction in human diabetic neuropathy has been questioned [51]. No abnormality was found in a series of 29 patients with diabetic neuropathy when axoglial dysjunction was assessed by quantifying the paranodal dimensions and by assessing high power EM micrographs for any alteration in the attachment of the terminal loops to the axolemma and change in the desmosome-like junction [50].

(a)

(b)

Figure 63.3 Electronmicrographs of a normal myelinated fiber (a) and a myelinated fiber showing axonal atrophy from a diabetic patient with neuropathy (b) (×8000).

attributed to remyelination and axonal regeneration [44]. Furthermore, in a detailed neuropathologic study of sural nerve biopsies from 6 control subjects and 16 age-matched diabetic patients with different syndromes of sensory polyneuropathy (6 with chronic painful neuropathy [CPN], 4 with newly presenting painful neuropathy [NPN], and 6 with painless neuropathy associated with recurrent neurotrophic foot ulcers

Unmyelinated fibers

The detailed morphologic assessment of unmyelinated fiber pathology requires electron microscopic morphometry to quantify axon density, size, and the density of unassociated Schwann cell profiles. It appears that unmyelinated fibers may be damaged early but show significant repair even in advanced neuropathy. Thus in a study of diabetic patients with minimal evidence of neuropathy the unassociated Schwann cell profile density (Figure 63.4) ($p < 0.04$) was increased suggestive of degeneration but was accompanied by an increase in the unmyelinated axon density ($p < 0.001$) with a reduction in the axon diameter ($p < 0.007$) and an overall shift of the size frequency distribution confirming the presence of axonal sprouts and hence regeneration (Figure 63.4(a,b)) [3]. Similarly, in a study of 15 diabetic patients with mild neuropathy, the percentage of unassociated Schwann cell profiles ($p < 0.0001$) and axon density ($p < 0.0008$) were significantly increased with a significant reduction in unmyelinated axon diameter ($p < 0.001$) with a shift of the size frequency distribution to the left ($p < 0.02$). In four young type 1 diabetic patients with severe autonomic dysfunction characterized by postural hypotension, fainting, diarrhea, and Argyll Robertson pupils, sural nerves demonstrated a marked reduction (6 +/− 4% of that in the controls) in the density of unmyelinated fibers [23]. Although, in a patient with severe postural hypotension and significant autonomic neuropathy there was still evidence of marked unmyelinated fiber regeneration in the form of axonal sprouts with a 77% increase in axon density and 62% reduction in axon diameter [24]. In a series of patients with T1DM subdivided into those with: (a) severe autonomic neuropathy and accompanying painless sensory neuropathy, (b) severe autonomic neuropathy and chronic painful sensory neuropathy, and (c) chronic or acute painful sensory neuropathy without autonomic neuropathy, the density and median diameter of unmyelinated axons was reduced in all three groups [22] and there was no correlation between the occurrence of pain and active degeneration or regeneration of unmyelinated axons [22]. Sural nerve biopsies from four diabetic patients with acute painful neuropathy and two in remission from this condition revealed evidence of unmyelinated fiber degeneration and regeneration in both groups, but remission from pain was found to be associated with less active unmyelinated fiber regeneration [52].

Microvessels

Microvascular disease contributes to the genesis of human diabetic neuropathy. Major pathologic abnormalities of the microvessels have been demonstrated in the majority of sural nerve biopsies from patients with IGT [53] and diabetic neuropathy [3,22,23,54–56]. Microangiopathy is most pronounced

(a)

(b)
Figure 63.4 Electronmicrographs from a control subject (a) and a diabetic patient (b) showing evidence of degeneration with a loss of axons (a) and an increase in the density of unassociated Schwann cell profiles (uscp), and regeneration in the form of axonal sprouts (as) (×7500).

in the endoneurial capillaries [57], but also occurs in the transperineurial [58] and epineurial [59] microvessels. The key features of the endoneurial microangiopathy are luminal narrowing [53,60], endothelial cell hyperplasia and hypertrophy [30,55,56], pericyte loss [30,56] and basement membrane thickening [30,54,56] (Figure 63.5(a,b)). Progressive endoneurial microangiopathy has been related to increasing severity of neuropathy defined by reduced nerve conduction velocity and loss of myelinated nerve fibers [54,55].

Extracellular matrix

The extracellular matrix comprises the space between the vascular and neural elements of the endoneurium and therefore
(a)
(b)

Figure 63.5 Electronmicrographs from a control subject (a) and diabetic patient with neuropathy (b) showing thickening of the basement membrane and reduction in luminal size of the endoneurial capillaries (×3000).

the content of this space may reflect what remains after nerve fiber loss, or may in fact give clues as to the pathogenic processes which lead to nerve fiber degeneration. In a detailed morphometric study of sural nerve biopsies from 15 patients with diabetic neuropathy, morphometric and immunohistologic
Figure 63.6 Electronmicrograph from a diabetic patient showing a collagen pocket (×12000).

studies were undertaken to characterize matrix changes in relation to neuropathology [61]. Increased endoneurial collagenization (type I and III but not type II) was observed in diabetic patients with a relative increase in type VI collagen around Schwann cells, types IV, V and VI collagen around endoneurial microvessels, and types IV and V collagen in the perineurium. The mean diameter of endoneurial collagen fibrils was increased, although the diameter of the fibrils within the basal laminal tubes surrounding degenerated myelinated fibers and within onion bulbs were of normal endoneurial calibre (Figure 63.6). Immunohistologic studies showed normal expression of laminin by Büngner bands with no difference in endoneurial fibronectin expression [61]. In a study of five sural nerve biopsies from patients with T2DM, advanced glycation end-products (AGE) were localized in the perineurium, endothelial cells, and pericytes of endoneurial microvessels and at the submicroscopic level as focal aggregates in the cytoplasm of endothelial cells, pericytes, axoplasm, and Schwann cells of both myelinated and unmyelinated fibers [62]. More recently in a small sample of five sural nerve biopsies from patients with T2DM, collagen V and VI were significantly increased in the endoneurium and only collagen VI was increased in the perineurium, whilst type IV collagen was normal. Laminin expression was normal, but tenascin expression was increased, especially around the axon myelin units of diabetic patients [63].

Variants of diabetic neuropathy

When diabetic patients develop neurologic deficits which are not consistent with diabetic sensorimotor polyneuropathy (DSPN) it is important to consider variants such as painless motor predominant neuropathy [64], diabetic lumbosacral radiculoplexus neuropathy (DLRPN), or chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Detailed pathologic and immunohistologic studies of sural [17,18], superficial peroneal [65], and intermediate cutaneous nerve of

the thigh (ICNT) biopsies and a recent post-mortem study [66] have provided novel insights into the pathophysiology of these less frequent, but clinically challenging variants of diabetic neuropathy (Figure 63.7).

In 1994, the landmark study by Said et al. changed our understanding of DLRPN [67]. A immunohistologic and pathologic study was undertaken in 10 type 2 diabetic patients with diabetic amyotrophy who underwent biopsy of the ICNT, a sensory branch of the femoral nerve [67]. The density of myelinated and unmyelinated fibers showed a variable decrease, with evidence of both axonal degeneration and demyelination on teased fiber studies. However, this was the first study to reveal ischemic nerve lesions in three, vasculitis and inflammatory infiltration in two, and mild inflammatory infiltration in four patients. A number of studies have followed which confirm an inflammatory basis for diabetic amyotrophy. Paraffin sections of sural nerves from 19 patients with DLRPN demonstrated a greater number of ICAM-1 positive vessels with TNF-α expression in Schwann cells and some macrophages as well as increased NFκ-B immunoreactivity in vessels and endoneurial cells which correlated with the number of empty nerve strands and axonal degeneration in teased fiber studies [68].

A series of 22 diabetic patients with painful multifocal diabetic neuropathy due to root, plexus or nerve trunk involvement underwent biopsy of a recently affected sensory nerve. There was a marked reduction in both myelinated ($1340 +/- 1070$ vs. $8370 +/- 706$) and unmyelinated ($5095 +/- 6875$) nerve fiber density (per mm^2), due primarily to axonal degeneration ($34 +/- 31\%$) which was associated with a necrotizing vasculitis of perineurial and endoneurial blood vessels, perivascular mononuclear cell infiltrates, and endoneurial hemorrhage [69].

In a recent study, of an initial cohort of 470 patients, detailed neurologic evaluation and nerve biopsy assessment was undertaken in 23 patients with a slowly progressive, severe, painless, symmetrical, motor predominant (∼50% in wheel chairs due to weakness) neuropathy, 33 patients with DLRPN, and 25 patients with CIDP. Examination demonstrated pan-modality sensory loss, autonomic abnormalities, and an axonal neuropathy. The nerves studied by biopsy were not specified, but one would assume that these were sural nerves and they demonstrated a reduction in myelinated fiber density, which was severe in 8/23, multifocal (11/23) and confirmed to be axonal degeneration on teased fiber studies, but with evidence of regeneration in the form of regenerative clusters (16/23). There were associated alterations in the epineurial vessels (23/23), vessel wall inflammation (15/23), and microvasculitis (3/23) (Figure 63.7). In contrast, CIDP biopsies revealed demyelination and onion bulbs without axonal loss or microvasculitis.

Given the possible association and increased incidence of CIDP in diabetes [70], a study of sural nerve biopsies from 10 patients has demonstrated epineurial perivascular T-cell infiltrates and immunoreactivity for matrix metalloproteinase-9 in diabetic patients with CIDP which was absent in patients with DSPN alone [71]. Indeed using a cut-off, of 24%
Figure 63.7 Light microscopic image of a sural nerve from a diabetic patient with DLSPN showing epineurial vessel pathology (×500). (For a color version of this figure, please see color plate section.)

MMP-9-positive cells, CIDP could be detected with a sensitivity of 70% and a specificity of 100% in diabetic patients.

Skin biopsy

Skin biopsy, a minimally invasive procedure, allows morphometric quantification of intra-epidermal nerve fibers (IENF) most commonly expressed as the number of IENF per length of section (IENF/mm) [72,73] (Figure 63.8(a,b)). Intra- and inter-observer variability for the assessment of IENF density demonstrates good agreement [73,74] and IENFD declines with age and does not appear to be influenced by weight or height [75]. An international consortium of investigators has recently compiled a normative database for IENFD in 550 healthy participants and shown an effect of age, but no influence of height, weight or BMI [76]. The blister technique is an alternative less invasive procedure which assesses innervation of the epidermis alone and shows good agreement with punch biopsy [77].

Diagnostic yield of IENF quantification

No study assessing the sensitivity and specificity of IENF in DSPN is available. However, several studies in SFN have included patients with DSPN. In 58 patients with pure SFN, a cut-off IENF density of ≤8.8 per mm at the ankle was associated with a sensitivity of 77.2% and a specificity of 79.6% [78]. Similarly, in 67 patients with pure SFN a sensitivity of 88.0% and a specificity of 88.8% have been reported [79]. In a study of 210 patients with SFN, which included 65 diabetic patients, the Z-scores and 5th percentile provided the highest specificity (98% and 95%, respectively) but a very low sensitivity (31% and 35%, respectively) compared to the ROC analysis (specificity 64%, sensitivity 78%) [80]. These findings suggest that the diagnostic yield of skin biopsy may depend on the reference and cut-off values selected and the definition of SFN adopted. IENF density correlates inversely with thermal thresholds. Some have reported a closer correlation with warm and heat-pain
(a)

(b)

Figure 63.8 Light microscopic image of a skin biopsy stained with PGP 9.5 showing normal IENF and dermal fibers (a) and a marked depletion of IENF with only dermal NF in a diabetic patient with neuropathy (b). (For a color version of this figure, please see color plate section.)

thresholds [78,81–83] compared to cooling thresholds [84,85] whilst others have reported the opposite, with a closer correlation with cold rather than heat detection thresholds [86,87]. A recent study has demonstrated no correlation between IENFD and the neuropathy symptom score, but interestingly an inverse correlation was demonstrated with the severity of pain assessed using the VASmax [88]. The correlation between quantitative sensory testing and IENF density therefore remains controversial.

The American Academy of Neurology, American Association of Neuromuscular & Electrodiagnostic Medicine, and American Academy of Physical Medicine and Rehabilitation have concluded that skin biopsy may be considered for the diagnosis of DSPN, particularly SFN, with a level C recommendation [89]. More recently, under the auspices of the European Federation of Neurological Societies and the Peripheral Nerve Society, revised guidelines on the use of skin biopsy concluded that IENF density

is a reliable and efficient technique to confirm the clinical diagnosis of SFN with level A recommendation [90].

Additional morphologic features of IENFs include the branch density, length and mean dendritic length; all show an early reduction which progresses with increasing neuropathic severity [11,91]. Several studies with serial skin biopsies in patients with SFN have shown that axonal swellings predict a decline in IENF density [92–94]. However, they occur not only in patients with SFN [95] but also in normal individuals [96] and isolated swellings with normal IENF densities have been observed in a variety of other neuropathies [96–99].

Diabetic neuropathy

In patients with diabetic neuropathy, the prevalence of abnormal NC, QST, and IENF was comparable [88]. However, IENF density was significantly reduced in patients with normal NC, suggesting early damage to small nerve fibers [10,12]. Although, a recent study has shown comparable abnormalities in electrophysiology thermal thresholds and loss of IENF in diabetic patients with mild neuropathy [88]. There is an inverse correlation between IENF density and the severity of DSPN, defined by the Neurological Disability Score [11,82,100] and the Neuropathy Impairment Score [12]. Additionally, IENF density appears to be lower in diabetic patients with painful compared to painless neuropathy [11,82,101]. A 1-year diet and exercise intervention program in patients with SFN and impaired glucose tolerance (IGT) led to increased IENF density [102]. However, no change was observed in 18 diabetic patients after pancreas/kidney transplantation (SPK) [103]. This may reflect the marked IENF loss at baseline [104], particularly in diabetic patients undergoing SPK and the slower regeneration rate of IENF in diabetic patients [105]. These data suggest that IENF loss is an early feature of diabetes, progresses with increasing neuropathic severity and may improve with appropriate intervention.

Sudomotor innervation

Recently, a novel stereologic technique has been applied in skin biopsies and showed a correlation between sweat gland nerve fiber density, neuropathic symptoms, neurologic deficits, and sweat production [106]. The same group have now developed the technique of double immuno-staining to demonstrate co-localization of sympathetic adrenergic and sympathetic cholinergic nerve fibers in cutaneous sweat glands and vasomotor and pilomotor systems [107]. An automated quantification technique has also been developed to expedite the quantification of sudomotor innervation [4].

Corneal confocal microscopy

Corneal confocal microscopy (CCM) is a noninvasive ophthalmic technique that enables the *in vivo* visualization of
Figure 63.9 Corneal confocal image from a control subject (a) and diabetic patient with severe neuropathy (b) showing a marked loss of corneal nerve fibers.

the sub-basal nerve plexus in Bowman's layer of the cornea and has been shown to detect small sensory corneal nerve fiber loss in diabetic neuropathy (Figure 63.9(a,b)) [108], idiopathic small fiber neuropathy [109], Fabry disease [110], and CMT1A [111]. Corneal nerve fiber damage correlates with IENF loss and severity of neuropathy in diabetic patients [11,112] and recently three independent tests of small fiber function [113], and appears more marked in patients with painful diabetic neuropathy [11]. A correlation between loss of corneal nerve fibers and the stage of diabetic retinopathy has also been demonstrated [114]. CCM may also be more sensitive than IENFD in detecting early damage [11] and repair after simultaneous pancreas–kidney (SPK) transplantation [104,115]. Thus corneal nerve fiber density improves 6 months after combined pancreas/kidney transplantation [115] and has more recently been shown to improve before neurophysiology, QST and IENFD, providing an early surrogate marker for repair in clinical trials of human diabetic neuropathy [116]. CCM has been shown to have high reproducibility [117,118], with reasonable sensitivity and specificity [119]. To enhance the ability and hence speed of quantification of small fiber pathology, an automated image analysis system has also been developed recently to rapidly quantify corneal nerve pathology [120,121]. Furthermore, a progressive loss of corneal sensation occurs with increasing severity of somatic neuropathy, providing a functional correlate of corneal nerve fiber loss in diabetic patients [122–124]. Therefore CCM may be an ideal technique to assess alterations in small nerve fiber pathology in relation to PDN and progression or regression of neuropathic deficits [125]. These properties provide a compelling argument

for CCM to be established as an FDA surrogate endpoint in clinical trials of human diabetic neuropathy.

Autonomic neuropathy

Chinmay S. Marathe, Liza Phillips and Michael Horowitz

Royal Adelaide Hospital/Centre of Research Excellence (CRE) in Translating Nutritional Science to Good Health, Discipline of Medicine, University of Adelaide, Adelaide, SA, Australia

Key points

- Autonomic neuropathy in diabetes is common but generally under-recognized, its manifestations diverse, and pathophysiology incompletely understood.
- Simple, inexpensive tests of cardiac autonomic function should be used widely.
- Cardiac autonomic neuropathy represents a major risk factor for mortality.
- Gastrointestinal autonomic neuropathy not only affects quality of life as a result of gastrointestinal symptoms, but impacts on glycemic control.
- Current management of the manifestations of autonomic neuropathy remains suboptimal.

Introduction

Diabetic autonomic neuropathy (DAN) may be defined as dysfunction of the autonomic nervous system in association with diabetes, or prediabetes, following the exclusion of other causes [1,2]. The autonomic nervous system innervates every organ in the body (Figure 64.1) and DAN may, accordingly, manifest as a diverse range of symptoms and deficits, including tachycardia, orthostatic and/or postprandial hypotension, exercise intolerance, nausea, vomiting, constipation, diarrhea, urinary retention and/or incontinence, sexual dysfunction, sweating abnormalities, increased glycemic variability, visual disturbance, and impaired awareness of hypoglycemia. There is a lack of standardization of diagnostic algorithms for the manifestations of DAN and, in general, screening for DAN has not been routine in clinical practice, which it should be. Despite the substantial adverse effects of DAN on both morbidity and mortality, it is arguably the least understood complication of diabetes, and current management options are limited [3]. This chapter focuses on the relevance of DAN, particularly in relation to the cardiovascular, gastrointestinal, and urogenital systems and the response to hypoglycemia; sudomotor function is addressed briefly. Broad considerations relating to the epidemiology and pathophysiology of DAN are provided initially, followed by a discussion of each of the major systems affected by DAN.

Epidemiology of Diabetic Autonomic Neuropathy

The prevalence of DAN remains uncertain given that it has been reported to range from 7.7% to 90% of the diabetic population [1,4]; this wide variation reflects inconsistencies in the definition of DAN, diagnostic methods (including their standardization) and the populations studied [1,5]. A conservative estimate would be that 20–40% of patients with diabetes develop dysfunction of the autonomic nervous system [2].

Pathogenesis of Diabetic Autonomic Neuropathy

While glycemic and metabolic control play important roles in the pathogenesis of DAN, the latter is heterogenous and poorly defined, which has implications for effective management (Figure 64.2). So-called "autonomic imbalance" is thought to arise from a loss of parasympathetic tone and/or a transient period of increased sympathetic tone, in the setting of decreased glucose tolerance, perhaps specifically glycemic variability [4]. There is a subsequent reduction in sympathetic tone. Obesity, inflammatory cytokines, oxidative stress, dyslipidemia, and adiponectin deficiency may contribute to autonomic imbalance. For example, obesity is associated with reduced heart rate variability, apparently independent of hyperglycemia [6], supporting the concept of "prediabetic" autonomic dysfunction.

Figure 64.2 Pathogenesis of diabetic autonomic neuropathy: proposed theories (see text for details).

The Diabetes Control and Complications trial (DCCT) [7,8] in type 1 diabetes (T1DM) demonstrated a reduction in DAN in the intensive control arm by 50% over a mean follow-up period of 6.5 years, reducing the prevalence of cardiac autonomic neuropathy (CAN) from 14% to 7%. A "legacy" effect was evident at 13–14 years following closeout of the study in the Epidemiology of Diabetes Interventions and Complications (EDIC) cohort with ongoing protection against CAN in the group randomized originally to intensive treatment despite comparable glycemic control [9]. In T2DM, the impact of glycemic control is less well characterized. The Steno-2 trial [10], a multifactorial intervention approach in patients with T2DM who had microalbuminuria (i.e., lifestyle modification and pharmacologic treatment to normalize blood pressure, glucose, and lipids), did, however, show a reduction in DAN after a mean treatment period of 7–8 years. Furthermore, in the Diabetes Prevention Program (DPP), in subjects at risk of diabetes who underwent intensive lifestyle changes there was an improvement in heart rate variability and a reduction in QT interval [11].

While the relevance of insights derived from models of diabetic somatic neuropathy remains uncertain, neuronal damage in DAN must ultimately be an outcome of direct neurotoxicity,

or secondary damage occurring as a result of impaired neuronal vascular supply. Hyperglycemia-induced activation of the polyol pathway is known to lead to the accumulation of sorbitol and changes in the Nicotinamide adenine dinucleotide:Nicotanimide adenine dinucleotide H (NAD:NADH) ratio, which may inflict direct injury on autonomic nerves [12]. "Nitrosative stress" (endothelial and neuronal damage due to accumulation of peroxynitrite from increased nitric oxide) is evident in experimental models of diabetes and has been linked to neuropathy [13]. Advanced glycation end-products (AGE) [14], activation of protein kinase C, and mitochondrial dysfunction may all lead to increased oxidative stress. Activation of protein kinase C also induces vasoconstriction and consequent nerve damage by restricting neuronal blood flow [15]. Recently, a receptor for AGE (RAGE) has been shown to be expressed on peripheral nerve tissue and it has been suggested that this interaction (AGE:RAGE) induces neuropathy by direct damage [16]. In a recent study of patients with T2DM, a higher incidence of autonomic neuropathy was associated with a reduction in levels of RAGE [17]. An autoimmune basis to DAN has also been proposed; lymphocytic infiltration [18], circulating immune complexes, activated T cells [19] and auto-antibodies to autonomic nerve structures [20–22] have been demonstrated in T1DM. A recent, prospective study in patients with T1DM reported that the presence of autoantibodies to autonomic nerves was associated with the development of CAN [23]. Finally, deficiencies of essential fatty acids, such as linoleic acid, have been proposed as relevant to the etiopathology of DAN [24].

Cardiovascular autonomic neuropathy

Cardiovascular autonomic neuropathy (CAN) [25], encompassing autonomic neuropathy involving the nerves innervating the heart and the systemic vasculature, represents a major risk factor for cardiovascular disease, as well as mortality, with a greater impact than traditional cardiovascular risk factors [26]. The vagus is the longest autonomic nerve and may be the first to demonstrate pathologic changes in CAN, resulting in a degree of parasympathetic denervation and a relative increase in sympathetic tone. Accordingly, early indicators of CAN are abnormalities in the spectral analysis of heart rate variability and impaired baroreflex sensing, which progress to resting tachycardia, impaired exercise tolerance and orthostatic hypotension. There are a number of other clinical manifestations of CAN, including abnormal diurnal and nocturnal blood pressure variation, diabetic cardiomyopathy, QT interval prolongation, intraoperative cardiovascular lability, ischemic stroke and, possibly, kidney disease [27]. Despite its significance, CAN is often overlooked during assessment of patients with diabetes [28], including those with known cardiovascular disease.

Epidemiology of CAN

The reported prevalence of diabetic CAN has varied widely, but is likely to be at least 20% [29]. A European multicenter study [30] evaluated the prevalence of CAN in the outpatient setting in both TIDM ($n = 647$, age 11–69 years) and T2DM ($n = 524$, age 16–72 years). CAN, diagnosed by strict criteria (≥ 3 abnormal cardiac autonomic tests), was evident in 16.8% of patients with T1DM, and 22.1% of patients with T2DM, while the prevalence of "borderline" CAN, defined by the presence of two abnormalities on cardiac autonomic testing, was 8.5% in T1DM and 12.2%, in T2DM [30]. There is strong evidence that CAN may occur in the prediabetic state, particularly in the setting of impaired glucose tolerance (IGT) [31].

Clinical sequelae of CAN (Figure 64.3)
Mortality

CAN is associated with an increased relative risk of death [29]. For example, meta-analysis of 15 studies indicated that when compared to those diabetic subjects without evidence of CAN, the presence of a single abnormality in cardiovascular autonomic function was associated with a relative risk for death of 1.20 (95% CI 1.02–1.41), which increased to 3.45 (95% CI 2.66–4.47) when two or more abnormalities were identified. In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, involving more than 8000 patients with T2DM, there was a strong association between CAN and both all-cause (2.14; 95% CI 1.37 –3.37) and cardiovascular (2.62; 95% CI 1.4–4.91) mortality, independent of traditional cardiovascular risk factors, the duration of known diabetes and medications [28,32]. This increased mortality appears to be primarily attributable to sudden cardiac death and there is evidence for an increased risk of cardiac arrhythmias [29,33]; the QT interval is prolonged in many diabetic subjects with CAN and is an independent predictor of mortality [33]. Abnormal epinephrine signaling and metabolism secondary to an imbalance in sympathetic and parasympathetic innervation to the myocardium predisposes to arrhythmias [29]. The imbalance in parasympathetic and sympathetic tone also disrupts the normal nocturnal parasympathetic dominance, resulting in nocturnal hypertension, which is associated with increased cardiovascular mortality [29]. While impaired heart rate variability can be evident relatively early in the course of diabetes, resting tachycardia is now regarded as a late manifestation of diabetes with vagal impairment [4]. In patients with parasympathetic damage only, resting tachycardia (usually 90–100 beats per min, but sometimes as high as 130 beats per min) occurs, while the heart rate is likely to be around the upper limit of the normal range in patients with both parasympathetic and sympathetic damage [4]. Resting tachycardia represents an independent risk factor for cardiovascular mortality. Finally, Vinik and others have proposed a model linking CAN with myocardial dysfunction (Figure 64.3) [1].

Cardiomyopathy

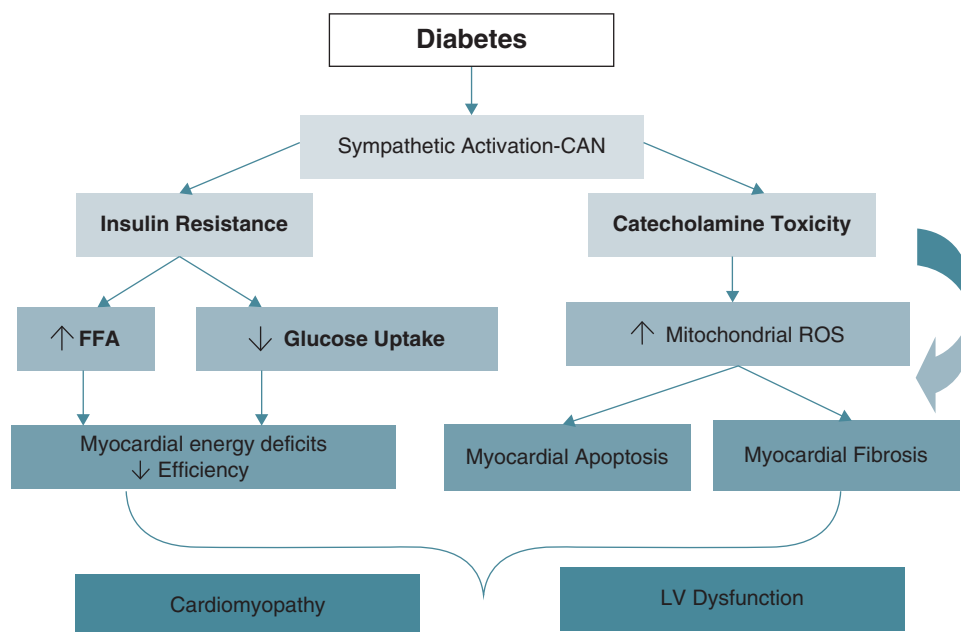
The heart rate, blood pressure and cardiac output adaptations to exercise are all attenuated in the setting of CAN, leading to a reduction in exercise tolerance [29]. Diabetic cardiomyopathy,


Figure 64.3 Proposed model linking CAN with myocardial dysfunction. Cardiac autonomic neuropathy (CAN); free fatty acids (FFA); reactive oxygen species (ROS); left ventricular (LV). Source: Pop-Busui 2012 [113]. Reproduced with permission of Springer.

that is, myocardial dysfunction that is not attributable to coronary artery disease, hypertension, and/or valvular heart disease, occurs frequently. Traditionally, diastolic dysfunction has been regarded as the early manifestation of diabetic cardiomyopathy [34]; however, the application of novel echocardiographic techniques and MRI technology [29] have established that changes in the left ventricle dynamics also occur. The myofibers within the myocardium spiral at an oblique angle, which results in rotation of the apical regions of the heart relative to the base during systole, a rotation referred to as "torsion" [29]. Recent studies have demonstrated that left ventricular torsion is increased in uncomplicated T1DM [35,36]. Further studies are required to define the role of CAN in the development of these left ventricular abnormalities.

Perioperative/intraoperative risk

Diabetes per se is associated with increased peri- and intraoperative risk, compounded in the setting of CAN which alters the hemodynamic response to induction and tracheal intubation during general anesthesia to increase the propensity for intraoperative hypothermia and cardiovascular instability [37].

Orthostatic hypotension

The baroreceptor reflex is a centrally mediated sympathetic response to standing, which induces peripheral vasoconstriction and reactive tachycardia. Orthostatic hypotension, defined as a decrease of greater than 10 mmHg in diastolic and/or greater than 30 mmHg in systolic, blood pressure within 2 minutes of standing [4], is a relatively late clinical manifestation of CAN [29]. Characteristic associated symptoms include dizziness, syncope, and visual impairment.

Postprandial hypotension

It is not widely appreciated that postprandial hypotension (PPH) (defined as fall in systolic blood pressure of ≥20 mmHg within 2 hours of a meal) occurs frequently in T1 and T2DM, particularly those with CAN, and may be more common than orthostatic hypotension [38]. PPH is associated with a number of adverse sequelae, particularly falls and cardio/cerebrovascular disorders [38]. Postprandial blood pressure control has recently been shown to be dependent on the rate of gastric emptying, such that relatively more rapid gastric emptying results in a greater fall in systolic blood pressure in patients with T2DM [39].

Assessment of CAN (Tables 64.1 and 64.2)

No single test is definitive for CAN. Simple, noninvasive cardiovascular autonomic reflex tests, first described by Ewing and Clarke, are used widely for the assessment of CAN [40]. Of these, changes in the R-R interval on the ECG in response to deep breathing, the Valsalva maneuver and postural change assess parasympathetic, while blood pressure changes following orthostatic provocation and the Valsalva maneuver assess sympathetic, function. These tests are generally regarded as the "gold standard" for clinical assessment of autonomic function because of their simplicity and accuracy—the heart rate response to deep breathing may have the greatest specificity [4]. The Valsalva maneuver should be avoided in patients with proliferative retinopathy. Defined reference values must be age-matched and it has been suggested that combining these tests with assessments of sudomotor function (to be discussed) may improve the precision of diagnosis [2]. While both the staging and diagnostic criteria remain to be standardized, the Toronto Expert Panel on Diabetic Neuropathy suggested

response. Measurement of muscle sympathetic nerve activity is technically demanding and only applicable to research studies. Scintigraphic imaging (measuring sympathetic function) has been used in research studies to assess cardiovascular autonomic function. The Toronto Consensus Panel on Diabetic Neuropathy (2010) emphasized the importance of evaluating patients for the presence of CAN, and proposed that screening for CAN should be performed at the time of diagnosis of T2DM, and 5 years after diagnosis in T1DM [42].

Management of CAN
Patients with diabetes and suspected, or confirmed, CAN should undergo cardiac evaluation prior to undertaking a new exercise regimen and cardiac stress echocardiography has been suggested as the investigation of choice in this setting [29]. Patients should also be advised to use their perceived level of exhaustion to guide maximal exercise, rather than rely on maximal heart rate parameters.

The main treatment strategy for CAN includes optimizing metabolic and glycemic control of diabetes. The diagnosis of early CAN, accordingly, provides an additional rationale for intensive blood glucose control. Although a number of pharmacologic approaches directed at the prevention or management of CAN have been evaluated, including angiotensin-receptor antagonists, metformin, C-peptide, and aldose reductase inhibitors [29], there is a lack of evidence to support their clinical application. Non-pharmacologic approaches specific to the treatment of orthostatic hypotension include behavioral

that at least two abnormal heart rate response tests be present for a definite diagnosis of CAN [2] and that the presence of orthostatic hypotension is indicative of severe CAN [29].

There are a number of other features of CAN, which are not traditionally assessed in the clinical setting. For example, both non-dipping of blood pressure, measured by 24-hour ambulatory blood pressure recording [41] and prolongation of the QT interval [33] may be markers of CAN. Spectral analysis of the ECG, a relatively novel method of evaluating CAN, transforms sequential R-R intervals into a sinusoidal function, which is analyzed to provide information about short- and long-term oscillations in heart rate variability [29]. Such tests must be performed under standardized conditions to minimize potential confounders including age, heart rate, food consumption, caffeine, smoking, the time of day, volume status, body position, and mental stress [29]. Tests of baroreflex sensitivity assess cardiac vagal tone and the sympathetic baroreflex

modifications, such as avoidance of sudden changes in posture, lower limb stockings, small and frequent meals, maintaining adequate hydration, and limiting salt restriction. Pharmacologic treatments include approaches that increase volume status (e.g. fludrocortisone, or erythropoietin in anemic patients) and those that augment sympathetic activity (e.g. midodrine) [43]. Slowing the rate of gastric emptying and carbohydrate absorption by interventions such as guar [44,45] and the α glucosidase inhibitor acarbose [46] has been shown to attenuate postprandial blood pressure decreases and may prove useful in the management of postprandial hypotension.

Gastrointestinal autonomic neuropathy

The modulation of gastrointestinal functions (motor, sensory, and secretory) is complex, involving an interplay between the autonomic and enteric nervous systems and the "pacemaker" interstitial cells of Cajal (ICC), which are located within the enteric smooth muscle [2]. The neurotransmitter, nitric oxide, plays a pivotal role at the cellular level [2]. Gastrointestinal autonomic neuropathy (GAN) may involve any organ within the digestive system, including the esophagus, stomach, gallbladder, pancreas, and small and large intestine. Both motor and sensory dysfunctions occur [2], but there is only a weak relationship between dysfunctions in different regions of the gastrointestinal tract. It has only relatively recently been appreciated that GAN has substantial implications for glycemic control in both T1 and T2DM.

Epidemiology of GAN
Most studies suggest that there is an increased prevalence of gastrointestinal symptoms among diabetics, perhaps particularly females and patients with T1DM [2]. Bytzer et al. [47] evaluated gastrointestinal symptomatology in relation to diabetic complications and glycemic control in 1101 subjects with (predominantly type 2) diabetes and reported that, when compared to those without diabetic complications, patients with at least one diabetic complication were more likely to report constipation, gastroesophageal reflux, dyspepsia, abdominal pain, and fecal incontinence. Gastrointestinal symptoms are associated with increased psychologic stress, including anxiety and depression, as well as impaired quality of life [48].

Pathogenesis of GAN
As with other manifestations of autonomic neuropathy in diabetes, the pathogenesis of GAN is multifactorial and incompletely understood. A number of etiopathologies have been proposed, including vagal parasympathetic dysfunction, enteric neuronal loss, defects in inhibitory neurotransmission including decreased expression of neuronal nitric oxide, and abnormalities of smooth muscle and the interstitial cells of Cajal [49,50]. A greater availability of human tissue, particularly derived from the NIH funded Gastroparesis Clinical Research Consortium, and the development of animal models, have recently provided important cellular insights into GAN. Loss/dysfunction of the ICC appears to be central to the pathogenesis of severe diabetic gastroparesis, and may occur as a result of increased oxidative stress leading to a reduction in heme oxygenase-1, the enzyme which gives rise to carbon monoxide [49]. A lack of growth factors, including both insulin and IGF-1, has been implicated in smooth muscle dystrophy and fibrosis, which are now recognized to occur in severe gastroparesis [49]. Abnormalities of the phosphatidylinositide 3-kinase (PI3K) signaling pathway have also been described in animal models of diabetic gastroparesis [51].

It is now recognized that gastrointestinal motor and sensory functions are affected acutely by metabolic and glycemic changes—what remains contentious is the magnitude and consistency of these effects. Diabetic ketoacidosis is frequently associated with nausea, abdominal pain, and gastric stasis—the latter may be marked. Gastric emptying is slowed in the setting of acute hyperglycemia (blood glucose ~15 mmol L^{-1}) [52]. Furthermore, in health and uncomplicated T1DM, gastric emptying is slower when the blood glucose concentration is at the upper limit of the physiologic rate (~8 mmol L^{-1}) when compared to euglycemia (~4 mmol L^{-1}). Conversely, insulin-induced hypoglycemia, is associated with a significant increase in the rate of gastric emptying [53] even in patients with CAN and gastroparesis, which is likely to represent an important counterregulatory mechanism. There is uncontrolled evidence that chronic improvement in glycemic control may normalize gastric emptying [54].

Diagnosis of GAN (Table 64.1)
Direct assessment of the gastrointestinal autonomic nervous system is usually not feasible, and abnormalities are traditionally inferred from assessment of cardiovascular autonomic reflexes and/or sudomotor function [2], although evaluation of the pancreatic polypeptide response to sham feeding has been used in some studies to assess the integrity of the abdominal vagus nerve. As will be discussed, the presence of CAN correlates relatively poorly with GI symptomatology, so GAN remains essentially a diagnosis of exclusion. While the absence of abnormality on assessment of GI motility does not exclude GAN as a cause of symptomatology, it may guide pharmacologic treatment.

The gold standard technique for assessment of gastric emptying remains scintigraphy, which has the capacity to quantify emptying and intragastric distribution of solid and liquid meal components concurrently. There have been attempts to standardize the methodology [55]. Ultrasound (2D and 3D) and stable isotope breath tests using noninvasive 13C-octanoic acid or acetate are acceptable alternatives [56]. While the absorption kinetics of paracetamol have been used widely, the technique is not recommended in view of its probable low sensitivity and capacity to evaluate gastric emptying of liquid only. Measurements of gastric emptying should ideally be performed during euglycemia (blood glucose 4–10 mmol L^{-1})—at a minimum, blood glucose concentration should be monitored.

There are established clinical tests to evaluate esophageal motor and sensory function, gastroesophageal reflux, small intestinal and colonic transit, as well as anorectal motor and sensory function [2].

Clinical manifestations of GAN
Esophageal dysmotility
Esophageal motility and transit are abnormal in ~50% patients with longstanding diabetes. Gastroesophageal reflux disease is frequent and may be secondary to disordered regulation of the lower esophageal sphincter, esophageal dysmotility and/or delayed gastric emptying, which may potentially be exacerbated by obesity. Patients frequently experience heartburn and/or regurgitation, and are at risk for pill-induced esophagitis. They should, accordingly, be advised to drink fluids immediately after medication. Dysphagia is an uncommon sequela of autonomic dysfunction and other pathologies should be considered in this setting.

Gastroparesis
Gastroparesis, defined as delayed gastric emptying in the absence of mechanical obstruction [57], is the most important manifestation of GAN. As well as the implications for upper gastrointestinal symptoms, the stomach is central to blood glucose homeostasis by regulating the delivery of nutrients into the small intestine and the release of the incretin hormones, GIP and GLP-1. In the US at least, the number of hospitalizations due to diabetic gastroparesis appears to be on the rise [58]. The prevalence of gastroparesis is reported to be between 28% and 65% in longstanding diabetes, although there have hitherto not been any true, population-based, studies (Figure 64.4). Gastric emptying may also be abnormally rapid [59]. Because the magnitude of the delay in emptying is often modest, the terminology "gastroparesis" could arguably be reserved for patients with markedly delayed emptying associated with

Figure 64.4 Gastric emptying, expressed as retention of solid meal (a) at 100 min and 50% emptying time liquid meal (b) (10% dextrose, 150 ml) in 86 patients with diabetes and 20 healthy control subjects. There is a wide inter-individual variation in gastric emptying in controls, and a high prevalence of delayed gastric emptying in the diabetic, although the magnitude of the delay in many cases is modest. Source: Jones 1995 [114].

significant gastrointestinal symptoms and/or impaired glycemic control. There may be a higher prevalence of gastroparesis in females and in T1DM, when compared with T2DM [60,61]. It is important to appreciate that, in health, gastric emptying shows a wide inter-individual [62], but relatively small intra-individual [63,64], variation so that nutrients enter the small intestine at an overall rate of $1-4\,kcal\,min^{-1}$, primarily as a result of inhibitory feedback arising from the small intestine. This inter-individual variation is, of course, increased in diabetes, which may account for what appears to be the little change in gastric emptying in patients with diabetes over time [64]. The relationship between delayed gastric emptying and CAN is weak [65]. The clinical features of gastroparesis include early satiety, nausea, vomiting, abdominal bloating and pain, impaired drug absorption, malnutrition and poor glycemic control, leading to impaired quality of life [2]. As with CAN, the relationship of upper gastrointestinal symptoms with the rate of gastric emptying is poor. The pathogenesis of symptoms remains poorly defined with disordered gastric motor/sensory function, acute changes in glycemia, gastric dysrhythmias, autonomic/enteric neuropathy, and psychiatric comorbidity all being invoked as relevant. Kassander, who coined the descriptive term "gastroparesis diabeticorum" in 1958, suggested that "the retention of stomach contents in a diabetic obviously may cause confusion as far as food intake and utilization are concerned" [66] and there is evidence that gastroparesis represents a risk factor for hypoglycemia in the early postprandial period in insulin-treated patients [67].

Management of gastroparesis
Despite improvements in understanding of the epidemiology and pathogenesis of GAN, treatment options for gastroparesis remain limited and the outcome is not infrequently, unsatisfactory. This is not surprising given that the underlying pathophysiology is heterogenous and, in general, the relationship between symptoms and gastric emptying is weak. Glycemic control and nutrition should be optimized. There is uncontrolled evidence that continuous subcutaneous infusion therapy may be beneficial [68]. Nutritional advice is currently based on anecdotal evidence and includes a reduction in portion size, increased frequency of meals, avoidance of insoluble fiber, and limiting carbonated beverages [25]. There is a rationale to minimize dietary factors known to slow gastric emptying, such as fat [25] and possibly, low-carbohydrate diets. If solid food is not tolerated, liquid meals should be introduced, given that liquid gastric emptying is usually relatively preserved. It is important to ensure that hydration, electrolyte status, and micronutrient balance are appropriate. While this is best achieved orally, more severe cases may require enteral, or parenteral, nutrition. Nausea and vomiting are common and antiemetics, including phenothiazines (e.g. prochloroperazine), 5 HT3 antagonists (e.g. ondansetron, granisetron), H1 receptor agonists (e.g. diphenhydramine), antidepressants (e.g. tricyclic antidepressants and tetracyclic antidepressants such as mirtazapine) and neurokinin-receptor antagonists (aprepitant) have

been promoted as useful based on uncontrolled studies [25]. Prokinetics, including metoclopramide, domperidone and erythromycin, which have different mechanisms of action, remain the cornerstone of gastroparesis treatment [69] although, not surprisingly, there is a poor correlation between their effects on emptying and symptoms. Tachyphylaxis is also an issue with erythromycin, a motilin agonist, limiting its long-term usage [70] and the effect of all drugs is likely to be attenuated by acute hyperglycemia [71]. Metoclopramide, which is a first-line treatment in diabetic gastroparesis and has central and peripheral antidopaminergic (D2) and cholinergic properties, should be given 15 min prior to meals and pre-bed; liquid and/or subcutaneous formulations are preferable [25]. Metoclopramide has significant adverse effects, including restlessness, hyperprolactinemia, a prolonged QT interval and extrapyramidal movement disorders. Accordingly, dosage should be minimized and drug holidays considered—the FDA has issued a "black box" warning in relation to tardive kinesia. Domperidone, which is not available in all countries, has comparable efficacy to metoclopramide [72], but a lower risk of adverse effects and acts predominantly as a peripheral D2 antagonist. Although cisapride is effective, use has been compromised by severe cardiac adverse events (prolonged QT interval, arrhythmia and death), so that it is now essentially unavailable [73]. The gastric hormone ghrelin accelerates gastric emptying in diabetic gastroparesis [74] and recently developed ghrelin agonists also have a gastrokinetic effect, with evidence of symptomatic improvement [75]. There have been encouraging open-label reports of the effects of injection of botulinum toxin into the pylorus, underpinned by evidence of pylorospasm in symptomatic gastroparesis [14]. However, recent controlled studies have failed to demonstrate efficacy and its use cannot be recommended [76]. Similarly, the promise of high frequency (∼12 pulses per min) gastric electrical stimulation, the Enterra device, remains unfulfilled [77,78] as the outcome of a multicenter study, involving 55 patients with refractory diabetic gastroparesis, was negative [79]. Pain is a difficult symptom to control and while opiates should be avoided, tricyclic antidepressants and gamma-aminobutyric acid *(GABA)* analogues (gabapentin and pregabalin) may have efficacy [80]. Surgery represents a last resort and there are no controlled studies. There is uncontrolled evidence that pancreatic transplantation may be associated with improvement in both symptoms and emptying [81].

Modulation of gastric emptying to improve glycemic control

The recognition that gastric emptying is a major determinant of postprandial glycemic excursions has stimulated the development of dietary and pharmacologic strategies to optimize glycemic control, particularly in T2DM, by modulating gastric emptying. Perhaps paradoxically the focus has hitherto been on concurrently slowing gastric emptying and stimulating the incretin hormone, GLP-1, as by acute administration of a whey protein preload given before a main meal [82]. Gastric emptying is of major relevance to the beneficial effects of some GLP-1 agonists on glycemic control—these drugs are now used widely in management of T2DM. Short-acting GLP-1 agonists, such as exenatide bd and lixisenatide, have a sustained effect to slow gastric emptying markedly, as does the amylin analogue, pramlintide [83]. In the case of short-acting GLP-1 agonists, the reduction in postprandial glycemia is related to the magnitude of slowing of gastric emptying which is, in turn, dependent on the baseline rate of gastric emptying [84]. Accordingly, these drugs probably do not slow emptying when the latter is already delayed. In contrast, long-acting GLP-1 agonists, such as liraglutide and exenatide once a week, do not have a major effect on gastric emptying with long-term usage, probably because there is tachyphylaxis to their initial effect to slow gastric emptying with sustained receptor stimulation [83]. These considerations are of relevance to the increasing use of the combination of basal insulin with a GLP-1 agonist in the management of T2DM [83].

Enteropathy: diarrhea, incontinence, and constipation

The prevalence of diarrhea, fecal incontinence and constipation all appear to be increased in diabetes when compared with the general population [2]. Diarrhea may reflect altered gastrointestinal secretory function and/or abnormalities in intestinal transit (which may be increased or decreased in GAN). Small intestinal bacterial overgrowth, which is a frequent complication of diabetic enteropathy, and celiac disease, must be excluded. The former may respond to intermittent, or chronic, administration of antibiotics and loperamide may also be useful. Constipation and fecal incontinence (the latter characteristically nocturnal) may occur concurrently. Disordered regulation of the internal anal sphincter and impairments in rectal sensation and compliance are likely to be important in the etiology of fecal incontinence [2]. Management of constipation is by traditional methods, involving laxatives, although some novel pharmacologic options are available [85].

Genitourinary autonomic neuropathy

Erectile / sexual dysfunction (Figure 64.5)

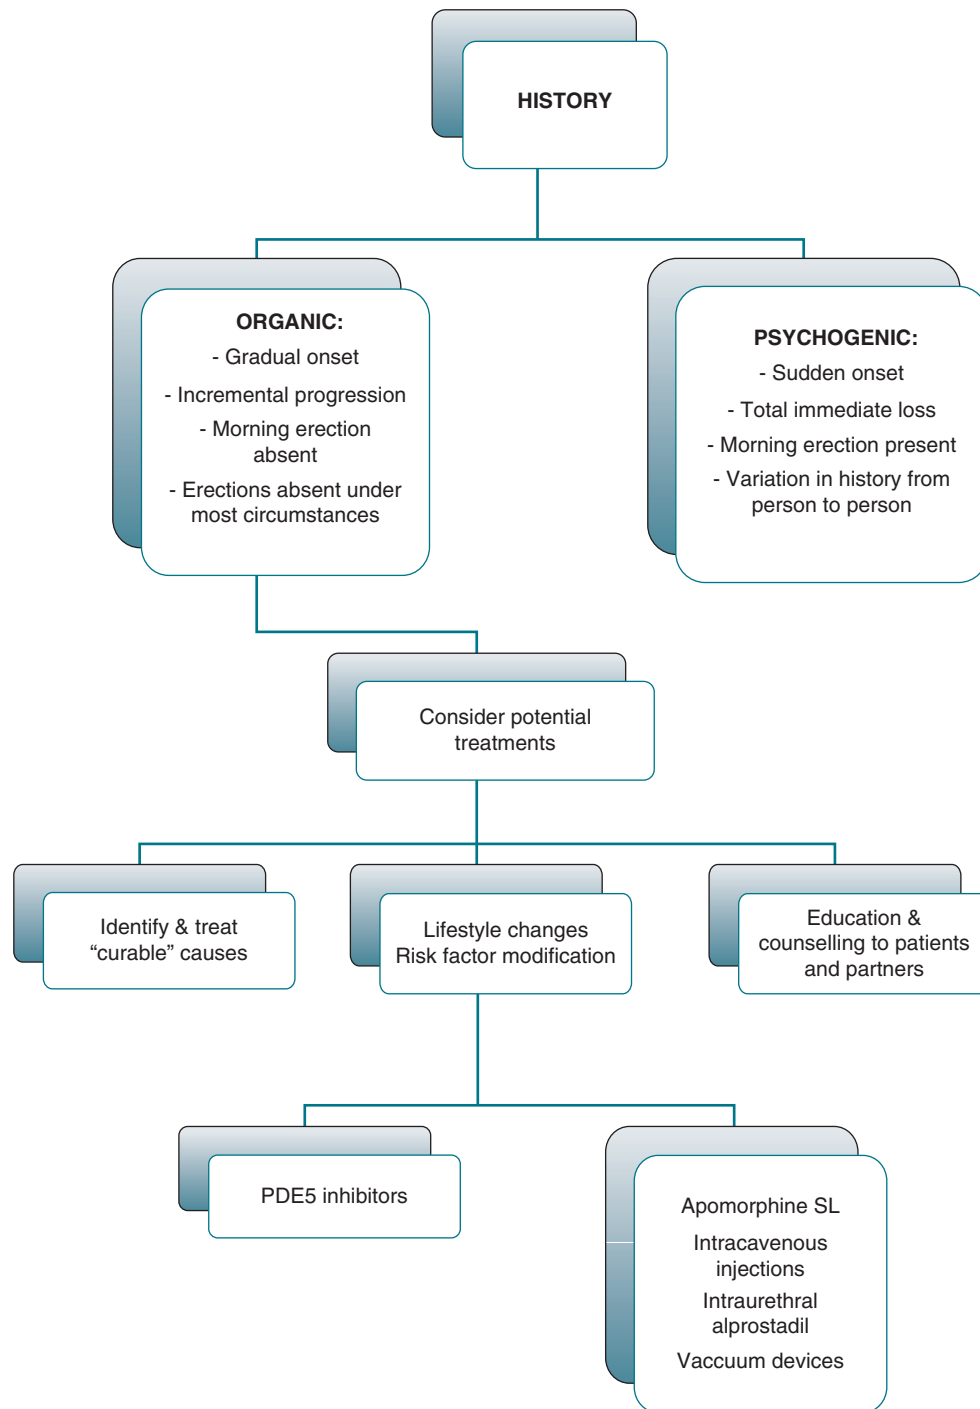
Erectile dysfunction (ED), defined as the "persistent inability to achieve or maintain an erection sufficient to permit satisfactory sexual intercourse" [86], is more common and severe in diabetic men when compared with nondiabetics [87], with a reported prevalence ranging from 35% to 75% [88–91]. ED impacts adversely on quality of life, personal relationships, and self-esteem [92]. Duration of diabetes, advancing age, macrovascular and microvascular complications, comorbidities including hypertension, obesity, dyslipidemia, hormonal deficiencies, and modifiable risk factors such as smoking, excessive alcohol intake, numerous drugs, and psychological disorder have all been associated with an increased risk of ED [1,92]. Some [93,94], but not all [95] studies suggest a direct association


Figure 64.5 Approach to management of erectile dysfunction. Source: Modified from Kempler 2011 [86]. Reproduced with permission of John Wiley & Sons.

between chronic glycemic control and erectile dysfunction. A strong association between autonomic neuropathy and ED [96] has been established, with the concept that disordered parasympathetic activity causes impaired relaxation of the smooth muscle of the corpus cavernosum leading to erectile dysfunction [97]. Retrograde ejaculation into the bladder is also

sometimes seen. Importantly, diabetic ED is a strong marker for future cardiovascular disease, perhaps particularly silent myocardial ischemia, and evaluation of ED should, accordingly, also include a thorough cardiovascular assessment [1,92]. The initial step in the management of ED is to attempt to discriminate between organic and psychogenic causes, although

the latter may be relevant even when there is an unequivocal organic component(s). The management of ED is multifaceted and summarized as an algorithm in Figure 64.5. Validated measures should ideally be used to characterize ED symptoms. ED may be relatively less responsive to treatment in patients with diabetes when compared with nondiabetic individuals. There is limited evidence to suggest that CAN is associated with female sexual dysfunction.

Bladder dysfunction

Bladder dysfunction occurs frequently (25–80%) in longstanding diabetes and, in the broadest sense, can usually be regarded as a manifestation of autonomic neuropathy [1]. A recent report from the DCCT/EDIC study indicates that CAN is associated with urinary incontinence and lower urinary tract symptoms in females [98]. Both autonomic (sympathetic and parasympathetic) and spinal somatic nerves are pivotal in the neurophysiology of micturition. Early damage to the afferent nerve supply may result in impaired bladder sensation, urinary retention and a higher threshold for initiating the micturition reflex. Damage to the parasympathetic efferent nerves, which mediate contraction of the detrusor muscle, results in a poor urinary stream, hesitancy and dribbling, while damage to the sympathetic efferent nerves, which innervate the internal sphincter of the bladder, may lead to overflow incontinence. Chronic bladder dysfunction is associated with an increased incidence of lower and upper urinary tract infections and renal impairment. Lower urinary tract symptoms should be assessed using a validated questionnaire and characterized by comprehensive urodynamic testing, with exclusion of other causes, such as prostatic hypertrophy in males.

Sudomotor dysfunction (including gustatory sweating)

The sweat glands, which are of two types: (a) eccrine and (b) apocrine, are innervated by postganglionic, unmyelinated cholinergic sympathetic C-fibers. Sudomotor dysfunction, which may occur early in the course of diabetic neuropathy [86] predisposes to dry skin, itching, and foot ulceration [99]. A number of tests have been developed to assess sudomotor function, including the thermoregulatory sweat test (TST), the quantitative sudomotor axon reflex test (QSART) which has been used most widely, and indicator plaster and silicone impressions. The sensitivity and specificity of these tests is variable and their combination, for example TST and QSART, may improve diagnostic accuracy [86]. While it is clear that assessment of sudomotor function provides additional information about autonomic function, its clinical relevance remains to be established.

Pupillary abnormalities

Autonomic neuropathy can affect pupillary function which may impact on vision/light sensitivity and cause an Argyll-Robertson pupil. Tests of pupillary function should be regarded as research tools [1].

Autonomic neuropathy and the response to hypoglycemia

Diabetic patients with established autonomic neuropathy are at particular risk of severe hypoglycemia [100]. Severe hypoglycemia is predictive of mortality in diabetes; for example, a 3.4-fold increased risk of 5-year mortality has been observed in those patients with self-reported severe hypoglycemia [101] and iatrogenic hypoglycemia remains a substantial limitation in the aggressive glycemic management of diabetes [102]. The normal counterregulatory mechanisms against hypoglycemia (including a reduction in insulin production by pancreatic β cells, an increase in glucagon by pancreatic α cells and an increase in epinephrine production from the adrenals) are impaired in T1DM, and longstanding T2DM [103]. Furthermore, hypoglycemia has the capacity to impair the autonomic and humoral responses to subsequent episodes of hypoglycemia. Recent antecedent iatrogenic (as well as exercise-induced and sleep-induced) hypoglycemia results in defective glucose counterregulation (reflecting reduced epinephrine release) and impaired hypoglycemia awareness (reflecting a reduction in sympathetic neural responses), potentially inducing a vicious cycle of recurrent hypoglycemia, or "hypoglycemia-induced autonomic failure" [104,105]. The impact of the latter can be dramatic and management focuses on the avoidance of hypoglycemia. A reduction in the epinephrine response to hypoglycemia may occur in the presence of apparently normal autonomic function tests [106–108]. While it has traditionally been considered that autonomic neuropathy does not play a role in the pathogenesis of hypoglycemia unawareness [109–111], there appears to be some overlap in their features [1]. It is likely, but not proven, that patients with CAN are particularly susceptible to the adverse sequelae of hypoglycemia, including life-threatening arrhythmias. Accordingly, in patients with severe CAN targets for glycemic control should probably be relatively higher.

Conclusions

The broad clinical implications of DAN reflect the complex and integral involvement of the autonomic nervous system with major organ systems. Despite its substantial impact on morbidity and mortality, DAN remains the least understood of the complications of diabetes. Autonomic dysfunction occurs very frequently, represents a major socioeconomic burden, and is generally underrecognized. CAN is of particular relevance given its strong association with cardiovascular morbidity and mortality. The diagnosis of CAN in diabetes and prediabetes needs to be standardized. Early recognition of autonomic neuropathy is imperative and feasible using simple, noninvasive tests of cardiovascular autonomic function, which should be used widely. Additional studies are required to better define the prevalence, natural history, pathogenesis and

clinical implications of autonomic neuropathy in diabetes and prediabetes with a view to the development of novel, and more effective, strategies for management.

CHAPTER 65

Connective tissue disorders in diabetes

Arlan L. Rosenbloom
University of Florida College of Medicine, Gainesville, FL, USA

Key points

- Osteopenia occurs early in type 1 diabetes and is associated with a wide variety of metabolic abnormalities related to bone metabolism.
- Bone mineral density is generally increased in type 2 diabetes.
- Fracture risk in adults with diabetes is increased, much more so in type 1 than in type 2.
- Dupuytren disease is far more common in diabetes than in the general population, with abolition of the male predominance in those without diabetes and appears to be an autoimmune T-cell mediated disorder.
- Stiff hand syndrome, diabetic hand syndrome (carpal tunnel syndrome), flexor tenosynovitis, and adhesive capsulitis of the shoulder with shoulder–hand syndrome are all associated with pain and have unmistakable diagnostic features.
- Only Dupuytren disease and limited joint mobility/Rosenbloom syndrome (LJM/RS) are painless limitations and only LJM/RS occurs in young people and is the only hand joint limitation that occurs exclusively in association with diabetes.
- LJM/RS is associated with increased risk for microvascular disease.
- The frequency of LJM/RS has dropped dramatically since the 1970s, presumably as a result of improved diabetes control.

Introduction

Connective tissue disorders in diabetes encompass the major long-term complications, which can be attributed to alteration in the quantity and quality of structural macromolecules of the extracellular matrix [1]. These alterations affect vascular basement membrane in the retina, kidney, heart, and skeletal muscle; muscle fiber basement membrane (e.g. with cardiomyopathy); nervous system basement membrane; and lens capsule and crystallin. This chapter reviews the abnormalities of interstitial connective tissue involving skeleton, joints, skin, and periarticular tissues that have been considered to be associated with diabetes.

Skeleton

Osteopenia

Direct comparisons among various studies of bone integrity in diabetes are difficult. Various techniques have been used to demonstrate reduced bone mass, including conventional radiographs, computerized tomography, single and dual photon absorption densitometry, radiographic measurement of cortical width (radiogrammetry), resonance frequency of the ulna, total body neutron activation analysis, X-ray microdensitometry, and since the mid 1990s, dual energy X-ray absorptiometry (DEXA). Controls in a number of reports are from previous studies or the literature, rather than concurrent and analyzed simultaneously. Finally, there are wide differences in age groups studied, as well as in diabetes types, and distinction is not always made between type 1 diabetes (T1DM) and type 2 diabetes (T2DM) in a particular study, or between insulin use and other treatment.

Type 1 diabetes

Since the early 1990s, almost all studies have used DEXA for determining bone mineral content (BMC) or bone mineral density (BMD). In comparable size and age adult populations with T1DM, BMD has been reported to be normal [2] or <2 SD from normal [3], in both studies correlating with duration and control measures. Other studies in adults with T1DM generally indicate modest reduction in BMD, either independently, or related to renal function, diabetes control, oral contraceptive use, duration of diabetes, or menopausal status [4]. In both children and adults, reduced BMD has been reported soon after diagnosis [4–6].

A specific mechanism for bone mineral loss in T1DM remains elusive. In the reported studies where diabetes control has been

examined, findings are mixed. While several studies of adults with T1DM show correlation of BMC or BMD with control, others do not [4]. Similarly, in children several studies show such a correlation, while more do not [4,7,8]. Similar disparities are seen when considering insulin dose and C-peptide levels, age, and duration of diabetes.

A wide variety of metabolic findings has been reported in association with osteopenia in T1DM, including hypercalciuria and hyperphosphaturia, increased serum concentrations of alkaline phosphatase, decreased levels of 1,25-dihydroxyvitamin D_3, and 25-hydroxyvitamin D_3, decreased parathormone (PTH), decreased osteocalcin indicative of decreased bone formation, and increased urinary deoxypyridineum cross-links as an indicator of increased bone resorption [4]. Rosenbloom et al. [9] found no correlation of bone mineral loss measured by single photon absorptiometry with serum concentrations of calcium, magnesium, or alkaline phosphatase. Hyperphosphaturia and hypercalciuria in T1DM may reflect poor diabetes control [10].

The mechanism for the influence of diabetes on bone formation has been suggested by an examination of the effect of advanced glycation end-products (AGE) on type 1 collagen, the predominant matrix protein of bone. *In vitro* studies have indicated that glycated collagen has reduced ability to promote differentiation of preosteoblasts to mature osteoblasts [11].

Type 2 diabetes
Adults with T2DM have normal or slightly elevated BMD compared to age- and weight-matched controls, particularly at the lumbar spine, hip, and radius [4]. A contributor to increased BMD in patients with T2DM has been noted in patients with T2DM who are taking HMG-CoA reductase inhibitors [12].

Fracture risk
Increased fracture risk has been noted for both T1DM and T2DM patients. Meta-analysis of studies that included over 1 million subjects has demonstrated an odds ratio (OR) for hip fractures in adults with T1DM of 6.3–6.9, but only 1.4–1.7 for those with T2DM. For spine fracture, the OR was 2.5 with T1DM. There was a 12-fold increase in hip fracture risk with nephropathy in T1DM. In the Women's Health Study, the OR for hip fracture was 12.3 for those with T1DM and 1.7 for patients with T2DM. Older patients with diabetes are at particular fracture risk because of greater likelihood of falling with visual impairment, neuropathy, cardiac arrhythmia, and age-related sarcopenia [4].

Hyperostosis
Increased BMD in T2DM in a number of studies may be related to the association of this disease with diffuse idiopathic skeletal hyperostosis (DISH), which may involve the spine as hyperostotic spondylosis (HS), the skull as hyperostosis frontalis interna, the pelvis as osteitis condensans ilii, the pelvic or other ligaments, or as large bony spurs at the heel or elbow [13]. There may be mild stiffness on arising in the morning, but spinal mobility is preserved and symptoms are usually absent. Heel and elbow pain can occur from calcaneal and olecranon spurs in about one third of affected patients and dysphagia has been described in 16% of those with hyperostosis of the spine.

While 2–4% of the general population may have hyperostotic changes, these changes are present in ~25% of the diabetes population. Pima Indians, with the world's highest prevalence of diabetes, also have a high prevalence of vertebral ankylosing hyperostosis, comparable to their diabetes rate of 50% [14]. Of those hyperostotic patients with spine changes, 83% are male and 30% are obese. One half of all patients with hyperostosis will have manifest diabetes or impaired glucose tolerance. Obesity and diabetes appear to operate independently in the determination of this condition. Radiography reveals preservation of the disc spaces with hyperostosis seen as a line of calcification in the right anterolateral portion of the spine, typically in the thoracic region. Radiolucency is seen between the deposited bone and the cortex of the underlying vertebral body. The principal differential diagnosis of HS is from ankylosing spondylitis, which occurs in a younger population and produces more serious problems, with morning stiffness and incapacitating loss of spinal movement. Radiographic differences are straightforward [13].

The etiology of hyperostosis in diabetes is not clear. It would be attractive to invoke growth hormone hypersecretion, in view of the similarity to acromegalic lesions, but growth hormone metabolism has been described as normal [13].

Joints

Osteoarthritis
Osteoarthritis and diabetes would be expected to be associated in T2DM through the common pathogenic factor of obesity. Additionally, there are a number of processes that have been described *in vitro* or with experimental diabetes, such as loss of glycosaminoglycans from articular cartilage, which may be pertinent to the pathogenesis [15]. Nonetheless, it has not been possible to establish an increased risk for osteoarthritis conferred by diabetes.

Osteolysis
Osteolysis (also known as diabetic osteopathy) of the forefoot is seen as a localized or generalized osteoporosis of the distal metatarsus and proximal phalanges. Pain is variable and there may be erythema over the joint, inevitably leading to a suspicion of cellulitis or osteomyelitis. The juxta-articular erosions may resemble those of rheumatoid arthritis and gout. The etiology of this lesion is unknown, and perfect reconstruction usually occurs spontaneously [16].

Rheumatoid arthritis
The genetic interrelationship between T1DM and rheumatoid arthritis has been studied in informative families by HLA haplotype analysis, suggesting co-inheritance [17]. Insulin resistance has been noted to be a feature of rheumatoid arthritis, together

with other features of the metabolic syndrome. The decreased insulin sensitivity has been quantitatively documented, correlating with C-reactive protein elevation and with dyslipidemia [17].

Skin and periarticular tissue

Scleredema diabeticorum

This condition occurs with a male preponderance (4:1) in middle-aged adults who have a long-standing history of poorly controlled diabetes and are obese. There is thickening of the skin with a predilection for the posterior and lateral aspects of the neck and upper back, with induration extending to the face and anterior and posterior trunk and potentially involving most of the body. Hyperplasia of collagen is seen on histologic examination, and one study has shown accumulation of glycogen in unmyelinated nerve fibers [18].

Dupuytren disease

Dupuytren disease (DD) refers to subcutaneous fibrosis of the palmar aponeurotic space of the hands. In those without diabetes the process is sex-linked with a 6:1 male predominance, and occurs only in people of European origin. Careful examination reveals that the true incidence of DD in diabetes approaches 40%, and, as with cardiovascular risk, the presence of diabetes abolishes the sex difference. Prevalence of DD in patients with diabetes has been reported to be from 20 to 63% compared with 13% in the general population [19]. DD is also more radial in the hands of those with diabetes than in those without diabetes, affecting the third and fourth digits predominantly instead of the fourth and fifth. Characteristic lesions may precede the development of diabetes and are present in 16% of newly diagnosed older patients [20]. DD lesions causing sufficient contracture to be removed by surgery were found to contain increased contents of water, collagen, and chondroitin sulfate, as well as increased proportions of soluble collagen and of reducible cross-links, indicating synthesis of new collagen. The lesions also showed increased amounts of type III collagen and increased hydroxylation and glycation of reducible cross-links, characteristics of granulation and scar tissues. Recent evidence places DD in the category of autoimmune T-cell-mediated disorders, which are relatively common with diabetes [21].

Stiff hand syndrome

This "severe and sometimes incapacitating form of vascular disease of the hands" was described by Lundbaek in 1957, in five patients with long-standing T1DM [22]. The problem typically began with complaints of tingling or burning sensations in the hand, with increasing symptoms and pain aggravated by movement, leading in two patients to invalidism. The subcutaneous tissue of the fingers and palms was stiff and hard, and in two patients there were marked nail changes. There was no muscle atrophy. Radiographic study revealed calcification of the arteries of the hand in all five cases. Skin biopsy showed very few elastic fibers, but no other changes. Only a single case report of the

actual syndrome has been subsequently published, suggesting that SHS may be an exceptional aggregation of diabetes complications affecting the hand (Dupuytren disease, neuropathy, atherosclerosis, diabetic hand syndrome) rather than a distinct differential diagnostic consideration [23]. Despite the lack of further reports of this dramatic condition, the term has been erroneously applied to the markedly different limited joint mobility (LJM/RS) that occurs in young patients and is without pain or paresthesias, is nondisabling, and lacks the dramatic skin changes and radiologic findings [24].

Carpal tunnel syndrome

Compression of the median nerve within the carpal tunnel at the wrist is the most common entrapment neuropathy, resulting in paresthesia of the thumb, index finger, and little finger, with pain that is often worse at night. Diabetes is the most common associated disorder, accounting for 5–16% of cases [13]. The condition is frequently referred to as the diabetic hand syndrome and, as with the stiff hand syndrome of Lundbaek, the term has been erroneously applied to LJM/RS.

In persons with diabetes, carpal tunnel syndrome (CTS) may not be simply due to nerve compression but a manifestation of diabetic neuropathy with decreased conduction velocity of both median and ulnar nerves with, in addition to typical thenar muscle atrophy, atrophy of the intrinsic and hypothenar muscles. The contractures involve the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of all fingers equally.

A literature review of 64 articles on CTS confirmed diabetes or a family history of diabetes as a primary risk factor, along with menopausal age, obesity, lack of fitness, smoking, alcohol intake, and osteoarthritis of the carpal–metacarpal joint of the thumb [25].

Flexor tenosynovitis

Flexor tenosynovitis (FTS), also known as "trigger finger" or stenosing tenovaginitis, can be congenital or hereditary in children, almost exclusively involving the thumb. In adults, it is estimated that one third of multiple palmar FTS is due to diabetes, although the prevalence in those with diabetes is not known [13]. There is marked female predominance, predilection for the right hand, and preferential involvement of the thumb, middle, and ring fingers. Fibrous tissue proliferates in the tendon sheath, particularly where the tendon is constricted in its passage through a fibrous ring or pulley or over a bony prominence, with swelling distal to this constriction and pain with movement of the enlarged segment through the narrowed ring. Palpable or audible crepitus may be present with movement; locking in flexion or extension occurs with impaction of the nodule proximal or distal to the thickened segment of tendon sheath [16].

Adhesive capsulitis of the shoulder and shoulder–hand syndrome

Thickening of the joint capsule and its adherence to the head of the humerus results in marked reduction in the volume of the glenohumeral joint. In some cases this periarthritis may precede,

accompany, or follow diffuse swelling, coldness, erythema, tenderness, and hyperhydrosis of the hand. Subsequently, swelling and vasomotor instability resolve, with the development of trophic skin changes and contractures. After weeks or months, the tenderness, swelling, and vasomotor dysfunction completely resolve, with residual atrophic or dystrophic changes, finger contractures and, occasionally, frozen shoulder with atrophy of the shoulder girdle muscles. Osteoporosis of the bones of the hand and shoulder is seen. In addition to shoulder–hand syndrome, this has been referred to as reflex sympathetic dystrophy, causalgia, post-traumatic osteoporosis, and Sudeck atrophy [13].

Adhesive capsulitis occurs at a younger age in those with diabetes, is typically less painful, but also less responsive to treatment and longer lasting than in those without diabetes. The prevalence is estimated to be 11–30% in those with diabetes and 2–10% in the nondiabetic population [19].

Limited joint mobility (LJM)/Rosenbloom syndrome (RS)

The initial observation of striking limitation of extension and flexion of the interphalangeal, MCP, and wrist joints, in association with short stature, thick, tight, waxy skin, delayed sexual maturation, and early microvascular complications, in three older teenagers with long-standing diabetes [26], was followed by the description of milder manifestations in 28% of 229 campers with diabetes aged 7–18 years [27]. Subsequent studies have reported prevalences of 9–63% among T1DM patients, depending on the age of the population and the duration of diabetes, as well as the examination techniques. A comparison of the findings in 1998 to those done by the same examiners using the same techniques 20 years earlier found a greater than fourfold reduction in frequency of LJM/RS together with a decrease in the proportion having more advanced changes, attributed to improved blood glucose control measures [28]. However, a subsequent report from England indicated a frequency of LJM/RS in the 1990s comparable to that reported in the original description in the 1970s in the US [29].

Several reports have described LJM/RS from a broad geographical range in T2DM also, with frequencies ranging from 25 to 76% [30].

There is no influence of sex or race on prevalence. In control pediatric populations, stiffness of the little fingers only was usually found in fewer than 4%, whereas older populations without diabetes may have as much as 25% involvement, probably related to occupation and aging. A significant independent contribution of cigarette smoking to both LJM/RS and DD has been described in adults with T1DM and T2DM.

Changes begin in the MCP and PIP joints of the little finger and extend medially; the distal interphalangeal joint may also be involved. Changes are also seen in the metatarsophalangeal joints [31] and larger joints, most commonly wrist and elbow but also ankles and cervical and thoracolumbar spine [32]. The limitation is painless, and nondisabling. Involvement of the foot can contribute to abnormal foot pressures and damage [33].

Examination and classification

The original method for demonstrating milder LJM/RS was to have the patient place the hands on a flat surface palm down with the fingers fanned; the examiner would then determine contact with the plane surface by viewing at table level. Normally, the entire palmar surface of the fingers makes contact [32]. A simpler method is to have the patient attempt to approximate the palmar surfaces of the interphalangeal joints with the fingers fanned (Figure 65.1). Whether either of these approximations is possible or not, the examiner extends the proximal and distal interphalangeal and MCP joints. In addition to finding these limited to less than 180° and 60°, respectively, the examiner may find resistance to the permitted movement [31,33]. Thickening of the tissues surrounding the limited joints and inability to tent the skin may also be noted, particularly over the dorsa of the fingers and hand. The examiner also attempts to extend the wrist maximally to at least 70° and the elbow to at least 180°. The ankle should flex maximally to at least 100°, the cervical spine lateral flexion should permit ear-to-shoulder juxtaposition, and thoracolumbar spine lateral flexion should be at least 35° in young people [34].
Figure 65.1 Inability to approximate the palmar surfaces of the fingers in a 14-year-old girl with diabetes for 7 years.

This examination will reveal obvious LJM/RS but, as noted, the clinical sensation of joint limitation without absolute reduction in maximum extension is quite subjective. Buithieu et al. [35] compared MCP and wrist maximal extension in 239 controls and 211 T1DM patients aged 9–30 years using a goniometer, and found a significant proportion of those without clinically apparent limitation to actually have MCP and wrist limitation, defined as less than 2 SD of the control mean. The 172 subjects without apparent LJM/RS included 25% with MCP limitation and 13% with wrist limitation. Similar findings have been reported from France [36]. Thus, earlier detection of LJM/RS may be possible through objective measurement. This is also likely for the associated changes in the lower extremity.

Mild limitation indicates involvement of one or two PIP joints, one large joint, or only the MCP joints bilaterally. *Moderate limitation* refers to involvement of three or more PIP joints or one finger joint and one large joint bilaterally. *Severe limitation* refers to obvious hand deformity at rest or associated cervical spine involvement [34].

Because LJM/RS may involve more than hand joints, the term "cheiroarthropathy" is not adequate, leading to such incongruous statements as, "Cheiroarthropathy … may also affect the large joints" [37]. Referring to this condition as "the scleroderma-like syndrome" [38] is also not appropriate because only the more severely affected individuals will have "digital sclerosis" [32]. It has also been called "Rosenbloom syndrome" which might be useful to be sure there is no confusion with the other finger joint limitation conditions associated with diabetes, as has been frequent in the literature [39–42].

Natural history

Cross-sectional studies demonstrate that duration of diabetes is the most important variable in the appearance of LJM/RS. However, when the time of development of joint changes is determined, age attained is much more important than duration of diabetes in the development of LJM/RS. The interval between detection of mild limitation and progression to moderate or severe changes varies from 3 months to 4 years, with a mean of 2 years. After this period, progression (if any) is very slow. Most do not progress beyond mild changes [43].

There was no correlation between loss of BMC by photon absorptiometry and the presence or absence of LJM/RS in children and adolescents, which is to be expected in view of the different timing of these findings in the course of T1DM [9]. One half of young patients affected with more than 5 years' duration of diabetes had moderate or severe limitation, defined as at least three interphalangeal joints or one finger joint and one large joint bilaterally. Approximately one third of the affected group had severe limitation, that is, involvement of all the fingers and often of the cervical spine as well [43]. In adult populations, about two thirds of patients affected had at least two fingers involved [44].

Hepatomegaly and proteinuria in many of the initial patients who were severely affected by LJM/RS and had associated thick, tight, waxy skin, suggested that LJM/RS was the result of poor control [26,32]. The only controlled study of metabolic regulation from the onset of diabetes until the occurrence of LJM/RS, in order to avoid the numerous biases of cross-sectional study, described a strong association of long-term control and the appearance of LJM/RS. For every 1% increase in average HbA1c from onset, there was an approximately 46% increase in the risk of LJM/RS [45]. As noted earlier, the greater than fourfold decrease in prevalence of LJM/RS and in severity in those few affected between 1976–78 and 1998 in the US can only be explained by the improvement in control measures [28]. A similar but less dramatic reduction in prevalence has been recorded for a young adult UK population (age 27 ± 1 years, $n = 204$) between the 1980s and 2002, from 43% to 23% [46].

Effects on growth

In individuals with more than 3 years' duration of diabetes, mostly with onset before adolescence (thus permitting sufficient time for growth failure to occur), 68% of subjects *without* LJM/RS, were below the 50th percentile for height rather than the expected 50%, and most of this discrepancy was below the 25th percentile (38% vs. expected 25%). Mild LJM/RS resulted in four times the excess below the 25th percentile (72%), and moderate to severe limitation was not associated with significantly greater deleterious effect on stature (77% below the 25th percentile). The small proportion above the 75th percentile was similar for those without LJM (12%), and with mild or more severe LJM/RS (both 10%) [43]. As with the marked reduction in frequency of LJM/RS, the associated impairment in growth and the modest growth impairment in those without LJM/RS virtually disappeared in the ~20 years following the initial study; of 175 children with greater than 2 years' duration before puberty and overall duration greater than 3 years, corresponding to the criteria of the earlier study, only 22% in 1998 versus 37% in 1982 were <25th percentile for height and of those few with LJM/RS, only 33% in 1998 were <25th percentile compared to 77% in 1982 [28].

Differential diagnosis (Figure 65.2)

The diagnosis of LJM/RS and its distinction from other joint problems should be straightforward, especially in young patients [30]. Nevertheless, since the original description, numerous reports have referred to the various conditions listed in Table 65.1 as "limited joint mobility," or have considered several of these conditions to be varying manifestations of the same process, using the terms for the distinctive diagnostic conditions interchangeably, in particular referring to LJM/RS as diabetic hand syndrome or stiff hand syndrome [47,48]. LJM/RS is easily distinguishable from DD, the only other condition involving the hand that is not associated with pain, by the absence of palmar fascial thickening and nodules, and by the finger distribution. DD is not seen in young patients; in older patients, DD and LJM/RS may be seen together [44]. All the other conditions are associated with pain and other characteristic findings, as

Table 65.1 Differential diagnosis of joint syndromes involving the hand in diabetes

Condition	Usual fingers involved	Pain/ paresthesia	Muscle	Frequency	Other distinctive features
LJM/RS	Begins 5th, extends radially	No	Normal	10–20 % of T1DM after 5 years and puberty	Not disabling; associated with thick, tight, waxy skin
Dupuytren disease	3rd, 4th	No	Normal	Up to 40% over age 40; 16% at diagnosis	Milder expression common in women; may precede diabetes
Flexor tenosynovitis	1st, 3rd, 4th	Yes	Normal	1/3 associated with diabetes	Marked female predominance; locking, disability
Carpal tunnel (diabetic hand)	All	Yes	Intrinsic, palmar atrophy	5–16% due to diabetes	Ulnar as well as median nerve involvement in diabetes
Stiff hand	All	Yes	Normal	Rare: T1DM >20 years	Disability; calcified vessels; hard palmar skin, soft dorsal
Shoulder–hand (reflex dystrophy)	All	Yes	Atrophy	Shoulder limitation in 10–20% of older T1DM, T2DM; reflex dystrophy unusual	Most bilateral; often associated with other hand syndromes

noted in Table 65.1. Rheumatoid arthritis is rarely associated with diabetes, and patients with LJM/RS do not meet the pain or inflammatory criteria for rheumatoid arthritis [17,30].

The superimposition of other hand syndromes on LJM/RS as patients age is not surprising, especially with prolonged duration. The presence of pain or paresthesia, neurologic findings, disability, finger locking, swelling, muscle atrophy, palmar skin or fascia thickening, or absence of greater involvement of the ring and little fingers could be indicators of additional problems. One would expect people with LJM/RS to be at

greater risk for other connective tissue proliferative problems and neuropathy. As noted earlier, generalized scleroderma can rarely be associated with diabetes, but should provide no diagnostic confusion. In older patients, osteoarthritis and occupation-related limitation should be easily distinguished by history and physical examination.

Neuropathy

Kennedy et al. [49] noted prolonged nerve conduction velocity for the ulnar and median nerves in older patients with LJM/RS, compared with those without limitation and comparable durations of diabetes. Also noted was decreased vibratory sense in both upper and lower extremities in the presence of LJM/RS. Starkman et al. [50] found that LJM/RS was associated with a 4.3-fold relative risk of clinical neuropathy in T1DM.

Pulmonary changes

The association of limited pulmonary capacity with LJM/RS was first noted by Barta in a single patient [39]. A study of 12 adolescents and young adults with severe LJM who were matched for age, sex, height, and duration of T1DM to 11 without LJM/RS, found that LJM/RS subjects had significantly less total lung capacity, thoracic gas volume, residual volume, forced vital capacity, and forced expiratory volume [51]. Similar findings have been reported from Hungary and Cuba. What cannot be ascertained is whether these individuals had limited pulmonary compliance, decreased mobility of the chest wall, or both.

Skin changes

Thick, tight, waxy skin, most prominent over the dorsum of the hands and the forearms, was noted in the initial patients and in about one third of those with LJM/RS described subsequently. This change was apparent only in those with moderate to severe LJM/RS [30,32]. In a study of 375 patients aged 7–25 years, skin changes were present in 34% of those without LJM/RS, in 70% of those with mild LJM/RS (involving only the fifth PIP joint) and in 100% of those with more severe limitation [52].

Ultrasound studies of 92 T1DM patients aged 20–38 years, with a wide range of disease durations, demonstrated that those with LJM/RS had thicker skin than those without limitation, who in turn had thicker skin than those without diabetes [53]. Skin thickness assessed by ultrasound measurement was also noted to correlate with LJM/RS in 80 children and adolescents [54].

Biopsy studies have shown thickening of the dermis and epidermis with accumulation of collagen and loss of skin appendages compared with control biopsies [30,50]. The pathologic features have been more carefully defined by Hanna et al. [55]. They found clinical evidence of skin thickening in 22% of T1DM patients and 4% of controls. Full-thickness skin biopsy specimens from the forearm were analyzed in nine patients with T1DM and thick skin, four patients with T1DM and clinically normal skin, four patients with progressive systemic sclerosis, and four normal control subjects. They defined distinct differences from sclerodermatous and normal individuals: the T1DM patients with thick skin showed active fibroblasts and extensive collagen polymerization in the rough endoplasmic reticulum. Unlike scleroderma, in which there is bimodality of collagen fiber sizes, the thick skin of diabetes demonstrated predominance of large fibers, a finding that was also present in those with diabetes who did not have thick skin. Thus, the fibrosis in these two conditions appears basically different. Biochemical studies are discussed in the following sections.

Association with microvascular disease

The initial seven patients with severe LJM/RS involving fingers and large joints included five with clinically apparent retinopathy or proteinuria before the age of 18 years [27,32]. In a unique longitudinal study of a clinic cohort in which the onset of LJM/RS and of microvascular complications could be documented, who had diabetes duration of more than 4.5 years (the shortest duration at which microvascular complications were noted), 82 of 169 patients had LJM/RS, of whom 41 also had microvascular complications, in contrast to only 10 of the 87 patients without LJM/RS. Severity of the joint limitation correlated directly with the frequency and severity of the microvascular disease. Actuarial analysis indicated an 83% risk for microvascular complications after 16 years of diabetes if joint limitation was present, but only a 25% risk in the absence of LJM/RS. The differences between the LJM/RS and non-LJM/RS groups could not be accounted for by differences in patients' ages or duration of diabetes. The 4.5-fold greater likelihood of microvascular disease in the group with joint limitation in this population indicated that LJM/RS identified a group exceptionally at risk for the development of early complications [34].

Among adult Irish patients with T1DM, retinopathy was present in 52.4% with LJM/RS compared with only 12.3% in those without joint limitation. Those with LJM/RS and retinopathy had much longer durations of diabetes than those with LJM/RS and no retinopathy. To assess whether the presence of LJM/RS was a risk factor for the development of retinopathy, independent of duration of diabetes, two subgroups of 20 patients each, with and without LJM/RS, were matched for duration. Retinopathy was much more common in the group with LJM/RS (85% vs. 40%), with a highly significant difference in the prevalence of proliferative retinopathy—70% in patients with LJM compared with 15% in patients with normal joint mobility [56].

A similar attempt was made to correct for duration of diabetes in a young population of 311 subjects aged 6–27 years undergoing fluorescein angiography to determine the prevalence of early retinopathy. The relationship between LJM/RS and retinopathy was highly significant ($p < 0.0001$), and this was not due to the effect of duration on both complications: the interaction of LJM/RS, retinopathy, and duration was insignificant. The presence of LJM/RS was predictive of associated retinopathy at the level of clinical recognition (more than 10 microaneurysms);

43% of those with LJM/RS and more than 4 years' disease duration had retinopathy compared with 15% of a matched duration group without LJM/RS [57]. In the 45% of 110 Ethiopian patients with T1DM who had LJM/RS, retinopathy was found to be twice as frequent as in those without LJM [58]. Among 150 Joslin Clinic patients under 40 years old, of whom 75 had LJM/RS, the relative risk of retinopathy conferred by the presence of joint limitation was 3.7, and of preproliferative and proliferative retinopathy, 4.2 [50]. The largest survey reported, involving 375 persons aged 7–25 years, noted positive correlations between skin involvement, severity of joint limitation, and diabetic retinopathy, although the latter was evaluated only through the undilated pupil [50]. Another large study, of 357 subjects, noted significant association of LJM/RS with retinopathy and proteinuria [59]. Other studies of T1DM come from Spain, of patients aged 18–57 years, in which correction was made for age and duration of diabetes, in which LJM/RS was significantly associated with albuminuria and retinopathy and of 335 patients from Germany aged 14–40 years, 34% of whom had LJM/RS, which was significantly associated with higher albumin excretion rates and hypertension. LJM/RS was also an independent predictor of retinopathy only in men, and of macrovascular disease (increased intima-media thickness of the carotids and atherosclerotic plaques) only in women [30]. In a study of 12 adolescent patients with proteinuria or hypertension and LJM/RS, the increase in the mesangial matrix and basement membrane thickening on renal biopsy correlated with the severity of joint limitation [60].

Significant correlations between LJM/RS and microvascular disease have been reported with T2DM, but these correlations have been less impressive than in T1DM. This difference is particularly apparent in studies that involve both T1DM and T2DM [44,58].

Biochemical studies

Increased accumulation of dermal collagen that is relatively insoluble and resistant to enzymatic digestion has been recognized as a characteristic of connective tissue aging in both T1DM and T2DM. Skin biopsies from the lateral thigh of 23 patients with T1DM yielded 8 with less than 2.5% collagen extractable in $0.5\,\mathrm{mol\,L^{-1}}$ acetic acid. Compared with the 15 with more than 2.5% acid-soluble collagen, there was no difference in age or mean duration of diabetes. However, the rates of retinopathy (50% vs. 0%), LJM/RS (63% vs. 20%), skin changes (63% vs. 20%), HbA1c values greater than 12% (63% vs. 27%), and decreased vital capacity (57% vs. 0%) were all significantly different [61].

Skin collagen glycation is increased with diabetes but this does not correlate with the presence of LJM/RS [49,61] or microvascular complications [61]. This glycation correlates with HbA1c level, and reflects the ketoamine link, an early step in the non-enzymatic browning (Maillard) reaction that leads to stable end-products (advanced glycation end-products, AGEs). These AGEs are fluorescent and thought to be responsible for

increased cross-linking of collagen. Monnier et al. [61] demonstrated that skin collagen fluorescence increased linearly with age, but that 95% of 41 T1DM patients had abnormal increases for age and that their fluorescence of skin collagen correlated with the presence of retinopathy, nephropathy, and LJM/RS. In a comparison of Maillard reaction products and collagen-linked fluorescence in skin collagen from 39 T1DM subjects and 52 controls, a modest increase (33%) was seen over the age span from 20 to 85 years in the controls. In those with diabetes, there was a threefold increase in collagen fluorescence, which correlated strongly with HbA1c, but not with age, and twofold increases in the Maillard products [62]. These same investigators further demonstrated association of these findings with retinopathy and nephropathy, but not with LJM/RS [63]. AGE serum concentrations have been found to be increased in young patients with T1DM, correlating significantly with HbA1c, and to decrease with improved control, consistent with the early appearance of LJM/RS and its correlation with long-term control [45,64]. Most impressive has been the demonstration in the Diabetes Control and Complications Trial (DCCT) that indicators of skin collagen glycation, glycoxidation, and cross-linking, which correlated strongly with complications in the secondary intervention cohort, were markedly reduced in both cohorts undergoing intensive treatment compared to conventional treatment [65].

The accumulation of AGEs of the Maillard reaction, with increased cross-linking, dehydration, and condensation of collagen, is quite distinct from the more hydrated and soluble collagen with increased reducible cross-links in the thickened tissue of DD and shoulder capsulitis associated with diabetes. Thus, the suggestion that hypertrophied polyol pathway activity resulting in increased hydration of connective tissue, as in the connective tissue in DD, might also be associated with LJM/RS appears unlikely [66]. Indeed, aldose reductase inhibition has been ineffective in reducing the limitations in LJM/RS [67].

Constitutional versus metabolic considerations

The intuitive attribution of LJM/RS and associated skin changes to metabolic control along with the other long-term complications of diabetes has received extensive experimental support since publication of the DCCT results. The definitive demonstration of the importance of long-term diabetes control in the emergence of LJM/RS [45] and the marked decrease in prevalence of this complication with improved control measures since the 1970s [28] have indicated that the findings of the DCCT can be extended to the specific complication of LJM/RS.

Although no differences in HLA distribution between those with and without LJM/RS have been described [43,49], and there is no difference in frequency of organ-specific autoimmunity [43], a genetic component had been suggested by the observation of joint limitation in nondiabetic relatives of T1DM patients. Brice et al. [68] found 42% of 112 T1DM patients aged 2–12 years to have LJM, with 78% of those with duration of diabetes of more than 7 years being affected; this

is three to four times the prevalence reported by others for this largely preadolescent age group. This diagnostic exuberance may explain their finding among 214 nondiabetic first-degree relatives, that 35% of the relatives of children with LJM/RS were similarly affected as were 13% of relatives of those children without LJM/RS.

Rosenbloom and colleagues [69] examined 204 T1DM patients aged 7–23 years and 336 of their first-degree relatives. They also examined simplex and multiplex pedigrees with T1DM and normal controls. Only 1 of the non-diabetes-related normal controls had fifth finger joint limitation; 3% of 225 nondiabetic parents were affected compared with 21% of the probands. Of the 108 nondiabetic siblings, only 1 had fifth finger joint limitation. Three parents had adult-onset diabetes and had joint limitation. Of the nondiabetic relatives with joint limitation, none was related to a proband with LJM/RS and all tested were negative for islet cell antibodies. Among 11 T1DM multiplex families with at least 1 member having joint limitation, the concordance rate for LJM/RS was no greater than expected for age and duration of diabetes. Thus, the evidence for LJM/RS being a metabolic consequence of diabetes included the absence of limitation among nondiabetic first-degree relatives of probands, including of probands with LJM/RS, and that concordance for joint involvement was not increased in first-degree relatives with T1DM.

Further evidence for a metabolic explanation for LJM/RS in T1DM comes from its description in non-HLA-associated, nonautoimmune T1DM, in two siblings with the syndrome of diabetes insipidus, diabetes mellitus, and optic atrophy [70], as well as in two siblings with diabetes from infancy due to pancreatic hypoplasia [71].

Tissue culture studies provide the opportunity to examine genetically determined donor characteristics generations of cells removed from the donor metabolic milieu. The viability of cultured fibroblasts from two patients with severe LJM/RS and growth failure was found to be completely normal for age, indicating that there is not an inherent cellular defect in growth in these youngsters [72].

The essential (apparently) metabolic derangement for the development of LJM/RS and associated skin findings as well as other complications of diabetes that occur despite the type of diabetes (T1DM, T2DM, secondary) must require a constitutional predisposition, which is not specific. Monnier and colleagues [73] proposed a means by which this constitutional factor may be expressed. They noted that the age-related collagen-linked fluorescence in skin biopsies from long-standing T1DM reflecting AGEs was, as previously noted, greatly increased compared with controls. The rate of browning was not significantly different from normal in those without retinopathy but was 2.5 times greater in the presence of retinopathy. These findings suggested that there was a mechanism controlling the browning rate of collagen in those individuals who did not develop retinopathy.

An alternative metabolic pathway for ketoamine products could provide such a mechanism [74]. The oxidation of earlier glycation products to form relatively inert carboxymethyllysine rather than AGEs would reduce the ill effects of protein glycation. Differences in response to this process could explain different susceptibility to the development of complications.

Conclusion

The abnormalities in bone, joints, skin, and periarticular tissue described in this chapter cannot be attributed to a single pathogenic mechanism. As osteopenia is seen early in the course of diabetes and does not appear to worsen with duration, a basic metabolic abnormality concomitant with the development of hyperglycemia and unlikely to be related to other complications is probable. Vascular insufficiency associated with vessel calcification can explain the stiff hand syndrome, and neuropathy the carpal tunnel syndrome as it appears in diabetes, where it is referred to as the diabetic hand syndrome. The lesions attributable to connective tissue proliferation, involving palmar fascia (DD), the periarticular tissue (adhesive capsulitis of the shoulder, LJM/RS), the tendon sheaths (flexor tenosynovitis), and the skin, may have the most relevance to the long-term disabling or fatal complications of diabetes in which connective tissue of basement membranes is abnormal.

Although the lesions of diabetes complications are frequently compared to those of aging, the skin and periarticular lesions (and perhaps the osteopenia) of diabetes either are unique or differ substantially from comparable lesions in nondiabetic individuals. This is also true for the complications of the retina, the heart, the kidneys, and the peripheral nerves. LJM/RS is of particular interest because of its early onset, the associated skin and lung changes, the established relationship to microvascular disease, and the dramatic reduction in its frequency in T1DM during an era of improved ability to control glycemia.

The diabetic foot

Frank L. Bowling and Andrew J.M. Boulton

University of Manchester, Manchester Royal Infirmary, Manchester, UK

Key points

- Peripheral neuropathy is concurrent in 90% of foot ulcers and is a major contributor to diabetes-related foot ulcer development.
- Renal disease increases risk of foot ulceration and dialysis is a strong predictor of lower extremity amputation.
- A comprehensive diabetic foot examination is essential for appropriate assessment, prevention, and management of diabetic foot complications.
- Diabetes-related foot ulcers do not require cultures or antibiotic treatment in the absence of clinical signs of infection.
- Off-loading using a total contact cast is a highly effective treatment for diabetic foot ulcers and acute Charcot neuroarthropathy.

Introduction

There are currently an estimated 360 million people suffering with diabetes mellitus worldwide which equates to approximately 5% of the global population. Foot ulceration is a common complication of diabetes and at any one time 2–4% of the diabetes population is likely to have an active foot ulcer and more than half of these will become infected [1]. Eighty-five percent of infected diabetic foot ulcers progress to lower limb amputation after which 5-year mortality rates are significantly increased.

Many of the complications associated with diabetes are inextricably linked through abnormalities in microvascular and macrovascular function underpinned by the metabolic anomalies resulting from chronic hyperglycemia. As a consequence of the multisystem nature of diabetes, the development of foot lesions and subsequent healing will be influenced by the extent and severity of other complications including peripheral vascular disease, cardiovascular disease, cerebrovascular disease, retinopathy, renal failure, depression and a significantly reduced quality of life.

Management of diabetic foot ulcers (DFU) is a long and complex process that begins before ulcer formation through a program of prevention. The last decade has seen the development, dissemination and implementation of consensus guidelines which clearly illustrate the interventions necessary to tackle the issue of diabetic foot ulceration. However, the increasing prevalence of diabetes and escalating healthcare costs associated with managing the complications make it more important than ever that these guidelines are understood and implemented appropriately.

The development of a foot ulcer is not an inevitable consequence for patients with diabetes. Lesions arise from a combination of multiple factors and processes which can be modified in order to reduce risk of ulceration. This chapter will explore ulcer pathogenesis, risks for ulceration, and the assessment process as a means of reducing risk. Management of infected foot ulcers will be included in a discussion of general management of DFUs followed by Charcot neuroarthropathy (CN).

Incidence and prevalence of diabetic foot ulcers

A person with diabetes has a lifetime risk of foot ulceration of between 15 and 25% [2]. The North-West Diabetes Foot Care Study identified the annual incidence of new foot ulceration in community diabetes patients as 1.7% [3].

A DFU is the result of the interaction of multiple physiologic processes with a large number of risk factors. Peripheral vascular disease and distal symmetrical sensorimotor neuropathy are highly influential in the pathogenesis of ulcer formation. The identification of relevant risk factors is essential for all patients with diabetes.

Peripheral vascular disease

The frequency of occurrence of peripheral vascular disease (PVD) in diabetes mellitus has been established by a number

of prospective longitudinal studies. The diabetes audit and research study in Tayside Scotland (DARTS) reported the annual incidence of PVD in patients with type 1 diabetes (T1DM) was 5.5 per 1000 patients and 13.6 per 1000 patients for those with type 2 diabetes (T2DM) [4].

Diabetes was reported to be positively associated with PVD (odds ratio 2.8) in the National Health and Nutrition Examination Survey with 4.3% prevalence in the general population of the USA [5].

A community-based study of T2DM patients in Australia identified the prevalence of PVD at entry to the study to be 13.6% [6]. The incidence of new PVD at follow-up 5 years later was 3.7 per 100 patient-years. In addition PVD was identified as a strong risk factor for cardiac death and independently associated with raised total serum cholesterol and smoking.

With respect to foot ulceration in Europe, the Eurodiale study reported that peripheral arterial disease was present in approximately half of all patients with foot ulcers assessed at baseline which the authors reported to be a shift away from ischemic ulcers towards neuroischemic ulcers. Twelve percent of all patients had critical limb ischemia [7]. A study by Gershater reported that 45% of patients with a diabetes-related foot ulcer also had signs of severe neuroischemia characterized by systolic ankle pressure of 80 mmHg or a systolic toe pressure of 45 mmHg [8].

The specific role of PVD in ulcer pathogenesis is difficult to determine as patients are rarely involved in health care during the early, asymptomatic stages of the disease. The significance of this is illustrated in findings from a study investigating factors related to outcomes in neuropathic and neuroischemic foot ulcers. Ulcers diagnosed as neuroischemic following objective investigation for the study would not have been considered as neuroischemic in the absence of the objective testing [9]. However, microvascular defects such as arteriolar hyalinosis, sclerosis and basement membrane thickening are observed in diabetes subjects. Large vessel involvement (iliac artery, femoro-popliteal and infra-popliteal) as seen with occlusive disease may contribute to ulcer formation due to subsequent reduced foot perfusion.

Patients with PVD are reported to have prolonged healing times, increased rates of amputation, higher mortality, and more disabling comorbidities. Neuroischemic ulcers tend to be larger with increased deep tissue and bone involvement in comparison to neuropathic foot ulcers. The apparent differences in clinical characteristics and outcome have prompted the suggestion that neuroischemic ulcers may be an entirely different disease entity. Further epidemiologic studies are necessary to explore this possibility [7].

Foot ulcers in patients with PVD also appear to be at increased risk for infection. The presence of a foot ulcer with or without infection increases perfusion demand and the imbalance in supply may decrease the likelihood of healing.

Peripheral vascular disease clearly plays a significant role in diabetic foot ulceration the specifics of which remain unclear.

However, reducing the risks of developing PVD through education, smoking cessation, increased physical exercise, and healthy diet is likely to be of long-term benefit.

Diabetic peripheral neuropathy

Neuropathy describes the progressive loss of sensation as a result of axonopathy and demyelination of small and large fiber nerves. C-fibers contribute to pain and temperature sensation whilst A-delta fibers carry information about vibration and joint position sensation. The mechanisms behind neuropathy are thought to originate with multiple metabolic pathways arising as a result of hyperglycemia and dyslipidemia and it has been well demonstrated that intensive diabetes treatment can prevent further deterioration in complications such as peripheral neuropathy [10].

Diabetic peripheral neuropathy (DPN) can also affect the central nervous system as well as the peripheral nervous system and studies have demonstrated neurologic changes within the brain related to diabetes [11]. Furthermore, responses to pain in patients with DPN have been explored and compared against subjects with diabetes but no DPN and nondiabetic controls. Functional magnetic resonance imaging (fMRI) illustrated that there were significantly different patterns of activation in the cerebral cortex of patients when nociceptive heat stimuli were applied to the foot and thigh [12].

There are a wide range of risk factors for developing neuropathy and cardiovascular disease plays a major contributory role. The presence of cardiovascular disease and diabetes is also associated with increased mortality. Other risk factors related to neuropathy include increasing age, duration of diabetes, and poor glycemic control.

The development of neuropathy is not a foregone conclusion given that a number of the risk factors are open to modification. The possible health benefits associated with strict glycemic control were explored in the Diabetes Control and Complications Trial Research Group (DCCT) which demonstrated significant reduction in progression of complications including neuropathy, nephropathy, retinopathy, and cardiovascular disease [13].

Diabetic neuropathy exists in many forms depending on the distribution and symmetry of the pathologic processes. However, in relation to the foot there are two commonly occurring manifestations: distal symmetrical sensorimotor peripheral neuropathy and peripheral sympathetic autonomic neuropathy.

Distal symmetrical sensorimotor peripheral neuropathy

Distal symmetrical sensorimotor peripheral neuropathy is characterized by abnormality or loss of sensation in the foot and is broadly divided into painful or painless forms although it is possible to experience both simultaneously. A recent German

population-based study identified a prevalence of neuropathy of 28% in the diabetic population [14].

Sensory thresholds for the development of ulceration are not known and given the complex influence of other complications associated with diabetes, a finite value for ulcer formation may never emerge. Whilst thresholds are used for the purpose of screening assessments, it should be acknowledged that sensation may be present but is no longer functional as a means of protection.

Frequently reported symptoms include unpleasant, abnormal sensations such as pins and needles, tingling, shooting pains, stabbing pains, "like walking on marbles or barefoot on hot sand," extremes of heat and cold (see Table 66.1). In contrast, patients may experience a feeling of numbness, heaviness or not uncommonly, be completely asymptomatic despite having significant sensory deficits on examination of the lower limb. Some patients may experience a combination of painful and painless symptoms.

Diabetic peripheral neuropathy may alter gait patterns due to impaired sensory feedback (proprioception) during walking [15]. Decreased balance and coordination may have the potential to increase the risk of foot trauma, deformity, and/or falls. All of the above can disturb gait mechanics and a high stepping gait, stamping gait and drop foot gait may be apparent during mobilization.

The motor component of distal neuropathy involves muscle wasting and the smaller muscles of the feet are particularly vulnerable. Claw toes may be observed as a consequence of "unopposed pulley" of the long extensor and flexor tendons due to wasting of the small muscles of the foot. Claw toes and bunions increase the risk of ulceration due to their contribution to creating abnormal pressure distribution on the foot prompting callus formation and a focus for ulceration.

Peripheral sympathetic autonomic neuropathy

Autonomic dysfunction in diabetes can affect the cardiovascular system, gastrointestinal tract, urogenital tract, and skin. Anhydrosis in the foot can be identified by dry, cracked skin which can be prone to fissures and ulceration.

Autonomic dysfunction can also disturb precapilliary sphincter function causing arteriovenous shunts to open which can give the impression on examination of a well-perfused foot when in reality there is capillary ischemia. Venous pooling and edema may also be present. Thus the warm, dry, insensate foot is very much an "at-risk" foot.

Other risk factors for foot ulceration

Ulceration and amputation risk increases with age and duration of diabetes [3,16]. In Western countries, males have been associated with a 1.6-fold increased risk of ulcers and have a

Table 66.1 The variable manifestations of diabetic peripheral neuropathy

Stage of neuropathy	Characteristics
No neuropathy	No symptoms or signs
Chronic painful neuropathy	Burning, stabbing pains +/− pins and needles; worse at night. Absent sensation to several modalities. Reduced/absent reflexes.
Acute painful	Symptoms as above. Hyperesthesia common. May follow initiation of insulin in poorly controlled diabetes; signs minor or absent.
Painless with complete/partial sensory loss	Numb/deadness of feet or no symptoms; risk of painless injury, reduced/absent sensation; reduced thermal sensitivity, absent reflexes.
Late complications	Foot lesions, neuropathic deformity, nontraumatic amputation.

higher propensity for amputations compared to their female counterparts [17]. Europeans have a higher risk of ulceration and subsequent amputation than those within the Indian subcontinent Asia or of African Caribbean descent [18].

Patients with a past history of ulceration or amputation are at the highest risk of recurrent ulceration [16]. Poor vision as a result of retinopathy is a predictor of foot ulceration [3].

Peripheral edema causes a restriction in local circulation and has been associated with an increased risk of ulceration [19].

Any alteration in foot architecture exposes the foot to areas of high pressure. Clawing of the lesser digits, hallux valgus deformity, and plantar flexed metatarsal heads with distal migration of the plantar fat pad into the sulcus increase the risk of tissue breakdown in the insensitive foot [3].

The accumulation of callus from peripheral sympathetic dysfunction in neuropathy is highly associated with ulceration. Callus acts as a foreign body within the patients shoe and ultimately leads to tissue breakdown [20].

Nephropathy

Renal disease, even in the preliminary stage of microalbuminuria, is associated with an increased risk of foot ulceration [21]. For new dialysis patients, the strongest predictor of lower extremity amputation is diabetes with the incidence in the first year of treatment nearing 6%. There is a strong temporal relationship between commencing dialysis and an increase in the risk of ulceration as demonstrated by Game et al. 2006. This study was retrospective and comparisons were made between patients before and after commencing dialysis. The authors reported a steep increase in the incidence of foot ulceration after initiating renal replacement therapy relative to the pre-dialysis period [22].

The majority of studies reporting an association between nephropathy and diabetic foot ulcers had not made a distinction

between patients with renal impairment receiving dialysis and those with renal impairment not receiving dialysis. In 2010 dialysis was reported as an independent risk factor for foot ulceration in patients with diabetes and renal impairment [23]. Furthermore, long-term hemodialysis has been demonstrated to undermine the ethnic protection against neuropathy and foot ulcer risk that has previously been indentified in patients with diabetes but not having dialysis [23,24]. The physiology underlying the relationship is yet to be established but could be related to metabolic changes associated with dialysis, long periods lying down or staying in one position whilst undergoing dialysis and the overall shift in disease management towards the renal system possibly to the detriment of other care needs.

Incidence of neuropathic foot ulcers

The relationship between neuropathy and diabetic foot ulceration has been firmly established by decades of research. Data from population- and clinic-based studies concur that the prevalence of neuropathy in patients with diabetes stands at approximately 25–30% [25]. The DCCT Research Group reported an incidence of 7% for those enrolled to receive the intensive treatment regime and 5% for those in the conventional treatment arm. Furthermore, the incidence was seen to increase over time and reassessment at 13–14 years after the DCCT closed reported an incidence of 22% for those in the intensive treatment group and 28% for those in the conventional group [13].

The EURODIAB IDDM Complications Study obtained a baseline prevalence of 28% for neuropathy in T1DM with a quarter of subjects having developed distal peripheral neuropathy over a 7-year period [26].

The North-West Diabetes Foot Care Study calculated an annual incidence of 6% for foot ulceration associated with neuropathy in comparison to those without neuropathy who had an annual incidence of ulceration at 1.1% [3].

Neuropathy is concurrent with 90% of foot ulcers as identified in the North-West Diabetes Foot Care Study whilst a study of the vibration perception threshold as a predictor of ulceration identified that patients with a moderate to severe sensory loss had a sevenfold annual increase of ulceration compared to those with normal sensation [27]. Patients with neuropathic diabetic foot ulcers have a 7% increased risk of amputation in the following 10 years [28].

The pathway to foot ulceration

Diabetic foot ulcers are highly heterogeneous and as such the processes involved in ulcer formation do not lend themselves to a unitary, linear model of pathogenesis. As stated earlier, the main contributors are thought to be DPN, PVD, foot deformity, and altered pressures during gait. The Rothman model of causation has been used to determine the factors involved in ulcer formation and establish causal pathways for patients

with diabetes [19]. The most frequently occurring component cause was peripheral neuropathy with foot deformity followed by minor trauma. A component cause alone is insufficient to achieve the endpoint of a DFU, but when combined with other component causes such as minor trauma, a sufficient cause can be generated leading to ulcer development. The model allows for different combinations thereby producing a variety of pathways, for example a patient with altered sensation in the foot and clawed toes has been wearing footwear insufficient to accommodate the foot deformity and presents to the footcare team with an ulcer on the dorsal surface of the foot. The factors involved are component causes as follows: neuropathy + deformity + trauma. Minor trauma was identified as the only factor with the potential to act as a sufficient cause for ulceration, that is, could act alone.

Abnormalities in foot pressures and their distribution may also contribute to ulcer development especially involving the plantar surface of the foot. Extremely high pressures during ambulation can arise from intrinsic, extrinsic or behavioral factors such as alterations in foot structure, including soft tissues, inappropriate footwear, trauma, or walking barefoot. Elevated pressures are most commonly recorded for the forefoot although the mid-foot and heel can be affected.

Patients from other clinical groups such as rheumatoid arthritis also demonstrate abnormal plantar foot pressures during mobilization related to bony prominences but do not have a tendency to ulcerate. This is assumed to be due to their ability to modify their gait in order to avoid loading a vulnerable area of the foot [29]. The patient with diabetes and peripheral neuropathy has the disadvantage of having lost the protective sensation that would prompt a change in gait or choice of softer footwear. Continued weight bearing and exposure to repetitive high pressures can therefore lead to ulceration.

The identification of causative pathways leading to ulceration in the foot highlights the areas in which to target prevention strategies.

Identification of the high-risk foot

The patient with diabetic neuropathy has lost the mechanisms that connect the individual and their feet with the environment. In the absence of this close relationship the foot becomes vulnerable necessitating a shift to the visual system as a means of monitoring integrity of the foot. This task can be performed by healthcare staff during annual reviews but the patient also has a responsibility to regularly monitor their own feet if able to do so. Guidance from the American Diabetes Association document on the "Comprehensive Diabetic Foot Examination" provides clarity on the structure and content of a robust assessment [30].

Assessment
The American Diabetes Association reported on the "Comprehensive Diabetic Foot Examination". This includes careful

history taking and a clinical examination consisting of a neurologic and vascular assessment.

History

A careful foot examination is the key component of the diabetic foot check.

- History of past or present neuropathic symptoms?
- History of any lower extremity vascular problem (intermittent claudication/rest pain/past history of bypass surgery or angioplasty).
- Past history of ulcer or minor/major amputation?
- Social factors (living alone, blood glucose control, cigarette smoking?).
- Other diabetic complications — especially visual impairment or end-stage renal failure (on dialysis or post-transplant).

Clinical examination

- Skin status — color, thickness, callus, dryness, cracking?
- Any signs of bacterial/fungal infection between toes.
- Breach of the skin/ulceration?
- Alteration in foot architecture, that is, claw toes, prominent metatarsal heads, loss of protective tissue on the sole of the foot.
- Reduced sweating.
- Small muscle wasting resulting in a high arch "intrinsic minus."
- Skin temperature? A unilateral warm swollen foot with intact skin consider acute Charcot neuroarthropathy until proven otherwise.
- Footwear suitability.

Neurologic assessment

Assessment for loss of protective sensation necessitates the use of two simple tests. In the first instance detection of pressure perception should be assessed using the 10 g monofilament (Bailey Instruments Ltd, Manchester, UK) which has been shown in several prospective studies to be a useful predictor of foot ulceration. Sites to be tested are the first, third, and fifth metatarsal heads and the plantar surface of the distal hallux. Failure to detect the perception of pressure at one or more sites in each foot would be considered to be an abnormal response [30].

The result of the monofilament test of pressure perception requires confirmation by a second perception test using one of the following:

- Vibrating 128 Hz tuning fork: this should be tested over the apex of the hallux bilaterally.
- Pin-prick sensation: the inability of a patient to detect pin-prick sensation can be tested using a disposal pin again over the apex of the halluces.
- Ankle reflexes: absence of ankle reflexes in either leg would be regarded as an abnormal response.

Vascular assessment

- Palpation of the posterior tibial and dorsalis pedis pulses: describe as either "present or absent."

- Doppler ultrasound probe can be useful to assess waveforms although vessel wall calcification can lead to a falsely elevated reading of the ankle-brachial index.

Infection and diabetic foot ulcers

Diabetes-related foot ulcers frequently become infected and the lifetime risk of developing a diabetic foot infection is estimated to be between 4% [31] and 7% [32] but in reality it may be higher. The unfortunate fact is the majority of amputations in patients with diabetes are preceded by an infected DFU [31] and may therefore be avoidable with correct diagnosis and management.

The majority of diabetic foot infections are highly likely to be caused by Gram-positive organisms. *Staphylococcus aureus* is the most common isolate although beta-hemolytic streptococci may also be present. Deep wounds, however, are largely polymicrobial in nature harboring a wide range of bacteria. Microorganisms such as gram-positive cocci, gram-negative rods, and obligate anaerobes may all be present within a single foot wound [33].

Diagnosis of infection in a diabetic foot wound can be problematic due to reduced clinical signs of the host inflammatory response particularly associated with neuropathy and ischemia. There is also the possibility of impaired immune responses in patients with diabetes as illustrated by impaired phagocytosis, reduced intracellular killing and increases in pro-inflammatory cytokines [31].

Whilst some patients with infected wounds will demonstrate pain, warmth erythema, raised temperature or raised CRP, approximately 50% may be asymptomatic (see Figure 66.1). Consideration of more subtle signs of infection may be necessary such as any unexpected changes in wound characteristics, new onset of tenderness, prolonged healing, and wound malodor,

Figure 66.1 Infected diabetic foot lesion. A 56-year-old patient presented with a painless, necrotic ulcer on the 5th toe of the left foot. On examination there was surrounding erythema and purulent discharge clinically suggesting infection. (For a color version of this figure, please see color plate section.)

alterations in discharge characteristics or poor granulation tissue. Moreover, some patients may present with unexpectedly poor glycemic control as assessed by home blood glucose monitoring, unaware that the cause is an infected neuropathic or neuroischemic foot ulcer.

Infection is suspected based on clinical assessment of the wound characteristics and if so antibiotic treatment should be commenced in addition to ongoing wound management. A tissue sample or deep wound swab should be taken for culture and sensitivity to inform a specific antibiotic regimen. Superficial cultures are inappropriate for infected DFUs due to probable contamination by colonizing bacteria during sample collection and therefore tissue cultures are advised.

Suitable antibiotics should include cover for both soft tissue and bone, for example flucloxacillin, cephalexin, and clindamycin, cover both bone and soft tissue, respectively. Sharp debridement, drainage of purulent discharge and off-loading form an essential part of the treatment combination.

Moderate to severe infection can be accompanied by systemic signs such as fever, tachycardia, pyrexia, uncontrollable hyperglycemia plus altered wound characteristics including additional cellulitis, gangrene, and abscess or wound probing to bone. Depending on the severity of the clinical presentation, admission to hospital for parenteral antibiotic administration may be necessary. Surgical debridement or resection of the infected structures may also be indicated.

Management of diabetic foot ulcers

Wound closure is the ultimate aim in the treatment of DFUs. The key elements of intervention include: removal of pressure, restoration of perfusion, eradication of infection if present and local wound care. These goals may be achieved through a combination of different techniques which are summarized in the following (see Figure 66.2).

Figure 66.2 Pressure-induced plantar ulceration. This 45-year-old diabetic patient with insensitive feet presented with shoe-induced ulcers on the toes of both feet. The hallux plantar surface showed build-up of callus and there were necrotic lesions on the apices of the 2nd and 3rd toe of the right foot. (For a color version of this figure, please see color plate section.)

Debridement

Hyperkeratotic tissue develops on the plantar surface of the foot as a result of shear pressure. Regular sharp debridement of excess keratin that forms callus provides a reduction in abnormally elevated plantar pressures and in doing so reduces the risk of ulceration [34]. Removing this overlying layer, and any necrotic tissue underneath, allows the ulcer to drain any fluid it contains and to begin to heal naturally from the base.

Wounds extending to bone and infected soft tissues require deeper and aggressive debridement to achieve removal of nonviable tissue and provide drainage of purulent discharge. Complete excision can significantly reduce the number of days taken to heal compared with ulcers managed conservatively. Strict off-loading is necessary after aggressive debridement.

Off-loading

Off-loading should be the first-choice treatment option for plantar foot neuropathic ulcers [35]. The aim of off-loading of neuropathic and noninfected neuroischemic plantar foot ulcers is to reduce pressure at the ulcer site through decreased weight bearing and redistribution of pressure over the wider area of the plantar aspect of the foot. Devices available include removable or fixed casts, orthotic devices, and custom-fabricated shoes.

The "total contact cast" (TCC) is the most effective off-loading device and has become the gold standard. Healing times are significantly shorter when total contact casting is used as opposed to other methods of off-loading. The success of total casting lies with the fact that they are nonremovable therefore the patient is obliged to wear them at all times. A study examining the activity patterns of patients with removable casts illustrated poor compliance with treatment and subjects wore the casts for only a minority of steps per day [36]. Thus the use of removable cast walkers rendered irremovable has been proposed for some cases [37]. In some specialist centers, a removable Scotchcast boot has also been used with some success. The boot gives support up to the level of the ankle, can be removed at night and the patient is able to continue mobilizing using a specialist sandal.

Wound dressings

Wound healing is significantly impaired amongst the diabetic population and further complicated by neuropathy and/or ischemia. The use of specialist dressings can provide favorable conditions for healing to occur by providing a moist protective environment. The range of dressings available is vast despite a questionable evidence base.

The basic requirements for any wound dressing product are effective absorption of exudate, thermal insulation, gas permeability and impenetrable to microorganisms. A product should not adhere to the wound itself thus preventing inadvertent removal of newly granulated tissue but at the same time material should be easily removed to allow visual monitoring of the wound it is protecting. Selection of the ideal dressing will depend upon the specific characteristics of the ulcer. Cleansing, removal

Table 66.2 Wound management products

Dressing	Description	Contraindications	Example
Hydrocolloid	Facilitate re-hydration and autyolitic debridement. Dry, sloughy, necrotic wounds. Promote granulation.	Infected wounds. Twice weekly change.	Aquacel (ConvaTec) Comfeel (Coloplast)
Hydrogels	Donates liquid to dry wounds and absorbs exudates. Dry, sloughy wounds. Autyolitic debridement.	Hydrogel sheets avoided in infected wounds	Intrasite gel (S&N Hlth.) Iodosorb (S&N Hlth.)
Silver	Antimicrobial. Colonization.	Sensitivity to silver	Acticoat (S&N Hlth.)
Vapor-permeable	Provide a moist healing environment. Mild exude.	Heavily exudating wound	Tegaderm (3M)
Foam dressing	Primary or secondary cover. Light and heavy exudates.	Remove if strike through occurs	Allevyn (S&N Hlth.) Lyofoam (Medlock Medical)
Odor absorbent	Absorbs odor. Malodorous.	Silver (sensitivity)	Actisorb (J&J)
Larval therapy	Debridement, promote granulation. Heavily sloughy necrotic wounds.	Increase in pain	Maggots (Zoobiotic)
Alginate	Hemostat. Heavy exudates.	Blockage. Loose fibers.	Kaltostate (ConvaTec)
Skin substitutes	Living skin. Obstinate wounds.	Colonized. Infected wound.	Dermagraft (S&N Hlth.)
Iodine	Antibacterial. Exudating wounds.	Iodine (sensitivity) Renal/thyroid conditions.	Iodosorb (S&N Hlth.)
Honey	Antimicrobial. Sloughy necrotic wounds. Autyolitic debridement.	Medical grade only	Mesitran (Medlock Medical)

of debris, granulation, vascularization and epithelization are the targets of wound management. As the wound progresses through different stages of healing it may be necessary to use a variety of different dressings (see Table 66.2). Products available can be divided into broad categories of those with debriding properties, antiseptic-based dressings, moisture providing and those that influence the healing process itself. A thorough knowledge of the products available and their theoretical attributes is necessary for selection of the most effective dressing.

Negative pressure wound therapy

The use of negative pressure wound therapy is becoming more widespread in the form of the V.A.C system. Studies have demonstrated faster rates of healing of diabetic foot ulcers and more wounds achieving closure [38]. Increased perfusion and promotion of granulation tissue formation are the reported benefits arising from the cell-stretching effect of negative pressure.

Growth factors and skin substitutes

Wound healing involves a complex interaction of a number of growth factors, one of which is platelet-derived growth factor (PDGF). There is growing interest in the potential application of growth factors to aid wound healing in DFUs. Becaplermin is recombinant PDGF ointment and its use has shown some slight benefit. Another growth factor is granulocyte colony stimulating factor (GCS-F) and it has been reported to improve resolution of infection in one pilot study whilst another study claimed it reduced amputation rates but further substantiation is required. Bioengineered skin (Apligraf) and human dermis (Dermagraft) are new types of biologically active implants for ulcers and contain human fibroblasts that deliver GFs and ECM components. However, the evidence base for many of these expensive therapies is weak and further large-scale randomized controlled trials are still needed, and should control as best as possible for the many potentially confounding variables, particularly offloading.

Multidisciplinary team input

The delivery of care for patients with diabetes-related foot complications has altered over recent years. The emphasis has

transferred from a centralized, core diabetes footcare team to a delegation of roles based in the community. Increased awareness among healthcare professionals and a shift away from hospital-based care has resulted in changes for the footcare team.

Screening for diabetes-related foot ulcers takes place at a community level with opportunities arising in a variety of different environments. The footcare team now extends to GPs, district nurses, practice-based nurses, and community-based podiatrists.

Successful management of diabetic foot complications depends upon achieving stability in all aspects of diabetes care. Strict glycemic control, stable kidney function, a functional visual system, stable blood pressure avoiding hypotensive episodes and intact cognition are all aspects of diabetes that significantly influence the success or failure of interventions for the lower limb. This can only be achieved through multidisciplinary working including across environmental boundaries.

Patients requiring a total package of care from a specialist diabetes footcare team will require a structured management plan in order to contend with the multiple comorbidities and complications associated with diabetes. A specialist diabetes footcare team should consist of a diabetologist, specialist foot surgeon (podiatric or orthopedic surgeon), specialist diabetes nurse, and podiatrist [39].

Improved outcomes, including reduced incidence of minor and major amputations have been demonstrated in a number of studies when care is delivered in this way. A recent study directly compared outcomes associated with care delivered by an established multidisciplinary diabetes team (MDT) with another hospital lacking a designated diabetes team. Results showed a significant reduction in major amputations performed on patients treated by the diabetes MDT (4.7%) versus 21.7% without MDT input ($p < 0.0001$). Mortality during hospitalization was also significantly different between the two groups at 2.5% for the MDT group and 9.4% for the controls ($p < 0.001$) [40].

Advice regarding glycemic control and maintenance of stable glucose levels will assist in achieving overall improvements in diabetes complications. Regular checks for retinopathy will reduce the risk of foot trauma occurring due to visual impairment.

Patient education

Patient education has long been advocated as a means of increasing patient understanding of their condition thereby increasing compliance and a subsequent reduction in diabetic foot complications (see Figure 66.3). Guidelines regarding the content and delivery of patient education programs have been included in clinical guidelines from the American Diabetes Association and International Diabetes Federation [41,42].

Comprehension of the features of peripheral neuropathy and its implications can be difficult for patients to accept but

Figure 66.3 Thermal foot wound. This 48-year-old female diabetic patient with peripheral neuropathy presented with extensive burns to the plantar surface of the metatarsal head region and hallux caused by walking on hot sand whilst on holiday. (For a color version of this figure, please see color plate section.)

without such acceptance daily footcare is unlikely to assume the important position it requires. Successful self-management requires motivation and compliance from the patient to accept a degree of responsibility for their own care; however, foot inspection can be problematic for obese individuals and those with visual impairment. Lavery et al. compared outcomes between patients given standard footcare review and advice, patients instructed in daily structured footcare examination versus patients taking daily temperature readings observing for significant increases as a prompt to contact healthcare services. Although compliance was poor across all the groups, there was a > fourfold decrease in the risk of developing a foot ulcer for patients taking their foot temperatures compared with standard foot management: if a significant difference between the foot temperatures was observed, patients were instructed to rest and contact their podiatrist for further management (OR 4.48; $p = 0.008$). Providing patients with an objective means of self-monitoring appears to provide a valuable method for encouraging ulcer prevention [43].

The use of inappropriate footwear, both incorrect size and those without inadequate cushioning are known to play an important role in the development of ulcers in patients with neuropathy. Tight shoes commonly lead to ulceration at dorsal deformities such as bunions or between the spaces of toes which have been crushed together. However, loose shoes can also lead to ulceration from the foot slipping inside, creating frictional force. Cushioning refers to the thickness of the soft material under the foot. Even simple sports trainers can reduce planter pressures by 50% compared to leather soles.

Additionally patients should be advised about other associated risk factors such as controlling high blood pressure, cholesterol, smoking cessation, and obesity. Not only will these measures

reduce patients' risk of ulcers, it will also lower their macrovascular complication risk.

Charcot neuroarthropathy

This condition is inextricably linked with distal symmetrical neuropathy as a result of diabetes although the exact mechanisms underlying the progression from neuropathy to tangible changes in foot architecture remain unclear. A number of hypotheses exist but evidence is often lacking.

With regard to incidence data is limited; one study that followed up patients with CN over 15 months reported incidence to be 0.3% per year [44]. An American study of diabetes complications in 2003 identified a total incidence of Charcot deformity to be 0.3% per year [45]. Information on prevalence is sparse; however, this may well be due to the fact that it is notoriously difficult to diagnose, there are no standardized criteria against which symptoms can be compared, and as a result CN can be overlooked as a possibility.

CN is characterized by osseous and joint destruction. Abnormalities may occur in the forefoot, midfoot, peritalar and ankle regions whilst avulsion fractures can affect the posterior tuberosity of the calcaneus. Patients have no awareness of the underlying changes in foot structure due to poor sensation therefore continue to mobilize. Foot deformity associated with CN is determined by the anatomical regions involved in the degenerative process. Changes in the architecture of the mid-foot can lead to collapse of the medial column. Hindfoot involvement can result in dislocation and fragmentation of the transverse tarsal joints and subtalar joint. Ankle joint fractures are less common than the former and latter regions but a more rapid progression in bone destruction results in poorer outcomes. There is a risk of ulceration as a result of increased and abnormally distributed foot pressures.

Although it was first diagnosed approximately 180 years ago, little is known regarding pathogenesis; however, there is general acknowledgment among medical professionals that there are four stages of the condition: a prodromal inflammatory phase when clinical and radiographic symptoms are minimal; a development phase with clinical and radiographic symptoms; a coalescence phase whereby clinical symptoms are marginally reduced but X-rays illustrate a wide range of degenerative osseus changes associated with advanced disease. The final remodeling phase can involve minimal clinical symptoms but fixed, residual deformity may be present whilst radiographically there is evidence of remodeled and new bone formation [46]. The process driving the change is uncontrolled inflammation and it is proposed that the initial inflammatory response is exacerbated by continued mobilization on the fractured joint. The subsequent prolonged production of inflammatory cytokines, RANKL, NF-kβ, and osteoclasts may be the route to ongoing osteolysis. Vascular calcification is also associated with

CN and a recent study confirmed a RANKL signaling pathway as a possible signaling pathway mediating this calcification. The study was *in vitro* and results appear to provide a link between vascular and bone metabolism [47].

Diagnosis of Charcot neuroarthropathy

Difficulties in diagnosing CN arise from ambiguous symptoms in the early stages for the condition. Acute local inflammation can be an early sign of underlying joint injury; however, this can also be indicative of cellulites, deep vein thrombosis, and acute gout. A temperature differential between the two feet of several degrees is likely whilst pedal pulses are usually bounding, all of which is characteristic of intact or even exaggerated blood flow to the foot. Plain radiographs can provide information on bone structure, alignment and mineralization. In the early stages of the disease subtle fractures may not be visible but as symptoms progress fractures, dislocation and subluxations may be more overt. Although plain X-ray films are valuable in working towards a diagnosis of CN the disadvantage is the delay between CN changes and visibility on X-ray film. Magnetic resonance imaging (MRI) can capture the early onset changes that may not be visible on plain X-ray films and is already known to have high sensitivity and specificity for osteomyelitis [48]. Positron emission tomography (PET) scanning is a possible modality for future imaging of complex foot pathologies in diabetes and may also be able to distinguish between osteomyelitis and CN.

Above all, the selection of investigations should be underpinned by a strong clinical suspicion of CN as a possibility [49].

Medical management of Charcot neuroarthropathy

Total immobilization and off-loading of the foot is the mainstay of treatment for acute, active CN and should be achieved through total contact casts. Use of crutches or a wheelchair can protect the foot further and avoidance of weight-bearing on the affected side is vital. Regular cast changes are necessary to avoid pistoning (movement within the cast) as edema subsides. Another offloading device is the removable cast walker although this will increase the risk of weight bearing on the affected limb. A stepwise return to normal footwear can be guided by improvements noted on imaging studies and reduction in clinical symptoms such as decreased edema, erythema, and improved skin temperatures [50].

Antiresorptive medications have been investigated as a possible treatment based on the high bone turnover that is associated with active CN. Bisphosophonates such as pamidronate and alendronate have been used with the aim of reducing bone turnover and although results were promising, sample sizes were small [51,52]. Large randomized controlled trials are required

to confirm efficacy prior to using pharmacotherapy in the treatment of CN [46].

Surgical management of Charcot neuroarthropathy

Surgical management of CN is based on expert opinion and case series. Rationale for surgery can include bone resection for osteomyelitis, removal of osseous prominences and foot deformities that cannot be managed through bespoke footwear. Tendon lengthening has been used to decrease the CN mid-foot deformity and following total contact casting favorable results are reported [53]. Reconstruction of deformities with internal fixation has also been reported but outcomes have been less positive given the poor bone stock and attenuated soft tissue [54].

Conclusion

Diabetic foot complications can arise as a result of the complex interaction between microvascular and macrovascular abnormalities. Peripheral neuropathy plays a major role in the development of foot lesions through loss of sensation. The absence of pain makes the foot highly vulnerable to intrinsic and extrinsic influences which can rapidly steer the patient down the pathway to ulceration.

Guidelines for the prevention and treatment of diabetic foot complications are invaluable in creating the standards of care necessary to achieve a reduction in lower extremity amputations globally.

Erectile dysfunction in diabetes mellitus

Michael H. Cummings and Rajesh Rajendran

Academic Department of Diabetes and Endocrinology, Queen Alexandra Hospitals Portsmouth NHS Trust, Portsmouth, UK

Key points

- Erectile dysfunction (ED) is extremely common in men with diabetes.
- Endothelial dysfunction and chronic inflammation have been implicated in both ED and cardiovascular disease (CVD).
- Diabetic men presenting with ED should be screened for hypogonadism and CVD.
- Phosphodiesterase type 5 inhibitors (PDE5i) remain first-line agents in the management of diabetic men with ED.
- Hypogonadism may occur in up to one third of diabetic men and testosterone replacement therapy can successfully restore potency in this group.

Introduction

Erectile dysfunction (ED) has been defined as the inability to achieve, maintain or sustain an erection firm enough for sexual intercourse [1]. There have been considerable advances in our understanding of the prevalence, pathogenesis and management of ED in the last few decades. It is now recognized that ED is perhaps the most common complication in diabetic men. There is also a greater understanding of the biochemical pathways that lead to vasodilatation and smooth muscle relaxation within the penile muscle facilitating tumescence. Abnormalities of these biochemical pathways have been identified in diabetic men with ED and have led to the development of a number of successful therapeutic options to treat the condition. In particular, the development of oral phosphodiesterase type 5 inhibitors (PDE5i) has revolutionized management not only because of ease of treatment but also the publicity around their launch has led to a wider understanding and more open discussion of the subject by patients and healthcare professionals. Prior to the launch of this class of drugs ED was considered a taboo subject

and both diabetic patients and their healthcare professionals were embarrassed to talk about the problem [2].

Previously, our understanding of ED in diabetic men has been hampered by studies which predominantly focused upon the general population with this condition. The knowledge that diabetes is the commonest cause of ED has led to a barrage of diabetes-specific studies being undertaken and this evidence forms the basis of this chapter examining epidemiology, pathophysiology, and clinical management.

Epidemiology

Despite the variation in populations studied and differing methodologies used to define ED, the overall prevalence of this condition is universally consistent, lying between 30 and 50% [2–7] in diabetic men and is far higher than in nondiabetic men where this figure does not exceed 20% [8]. In most studies, there has been little attempt to segregate findings in type 1 and type 2 diabetic subjects, however a few studies reported a similar prevalence of ED in both forms of diabetes [6,7]. Up to 40% of patients with ED may have underlying diabetes [9] and the incidence of new cases of diabetes has been shown to be around 11–12% [10,11] justifying the screening for diabetes in all previously undiagnosed patients presenting with ED.

Figure 67.1 demonstrates the exponential rise in ED with age and that the prevalence is always higher in the diabetic male compared with the nondiabetic population. The likelihood of ED in a 35-year-old diabetic male is equivalent to that of a 60-year-old nondiabetic male.

McCulloch et al. [4] showed that in diabetic men with ED, the most significant associations with its development were age ($p < 0.001$), treatment with oral hypoglycemic agents or insulin ($p < 0.001$), retinopathy ($p < 0.001$), symptomatic peripheral and symptomatic autonomic neuropathy ($p < 0.001$ and $p < 0.005$, respectively). There was also a weaker association

Prevalence of erectile failure in diabetes
Figure 67.1 The prevalence of erectile dysfunction in diabetic and nondiabetic men.

Table 67.1 Factors that may be associated with the development of erectile dysfunction in diabetic men

Functional and structural changes within the corpus cavernosum
Neurologic factors (changes within the parasympathetic nervous system—autonomic neuropathy, spinal cord lesions)
Vascular factors (atherosclerosis, arterial insufficiency, venous leakage, chronic inflammation and endothelial dysfunction)
Endocrine factors (hypogonadism, hypothyroidism and hyperthyroidism, hyperprolactinemia, GH deficiency)
Iatrogenic factors (drug use, alcohol abuse)
Psychological factors and psychiatric disorders
Primary penile abnormalities (e.g. Peyronie's disease)
Infections (balanitis)
Renal factors (renal failure and dialysis)
Others (penile trauma, tumors, etc.)

Table 67.2 Biochemical mediators of smooth muscle relaxation and constriction within the corpus cavernosum that may be affected in diabetic men with erectile dysfunction

	Relaxant	Contractile
Neuronal release		
	Nitric oxide	Noradrenaline
	Acetylcholine	
	Vasoactive intestinal polypeptide	
Local release		
	Nitric oxide	Endothelin-1
	Vasodilator prostanoids	Vasoconstrictor prostanoids
	Adenosine triphosphate	

with duration of diabetes, poor glycemic control, ischemic heart disease, and nephropathy. This cohort was re-examined 5 years later at which stage only 9% had regained potency [12], reflecting the progressive and nonreversible nature of the condition supporting the concept that the etiology is primarily organic in most cases.

In practical terms when attempting to forecast the likelihood of ED in diabetic men presenting for routine review, the probabilities are less than 5% in a 20-year-old male with no diabetic complications, 40–80% in a 40-year-old male with diabetic complications, rising to 80–100% in a 65-year-old male with diabetic complications.

Pathophysiology

Table 67.1 shows the factors that may contribute to the development of ED in the diabetic male. The most influential factors are considered to be local changes within the corpus cavernosum and aberrant neurovascular supply to this organ.

Changes within the corpus cavernosum

It is now recognized from studies of diabetic animal and human corpus cavernosum that there are abnormalities in the availability or effectiveness of several key chemical mediators involved in smooth muscle relaxation and constriction (Table 67.2), and that ED is strongly associated with endothelial dysfunction.

Nitric oxide (NO) is released either directly from the parasympathetic nerve terminal (PNT), or from the local vascular endothelium following stimulation by PNT released acetylcholine (ACh) and is integral, via its messenger cyclic GMP, in reducing intracellular calcium concentrations and facilitating smooth muscle relaxation. It has been demonstrated in diabetic men with ED that there is impairment in both parasympathetic nerve and endothelium-dependent mechanisms that mediate smooth muscle relaxation [13–15]. Diabetes impairs the activity of guanylyl cyclase, reduces NO synthase levels

and increases superoxide radicals, all leading to oxidative stress and free-radical damage finally leading to endothelial toxicity [16] and atherosclerosis. ACh administration was associated with a lesser degree of muscle relaxation in corpus cavernosum from diabetic men with ED and the degree of impairment was associated with the duration of diabetes [13]. Experimental studies in Wistar rats have provided a mechanism linking chronic dysglycemia and ED. When glycated hemoglobin was added to isolated corpus cavernosum from this animal model, Ach-mediated relaxation of this smooth muscle was impaired [17]. Moreover, this effect of glycated hemoglobin was mimicked by the addition of pyrogallol (a donor of superoxide anions) and partially reversed by the addition of L-arginine (the precursor of NO) [18]. In summary, these studies support the concept that dysglycemia impairs NO-induced smooth muscle relaxation and vasodilatation in the diabetic male with ED.

The PNT within the corpus cavernosum also releases another smooth muscle relaxant, vasoactive intestinal polypeptide (VIP), capable of reducing intracellular calcium via its messenger, cyclic AMP. It has been shown that VIP immunoreactivity is reduced in penile tissue of streptozotocin-induced diabetic rats [19] and diabetic men with ED [14]. It is possible that vasoactive prostanoids synthesized and released by the corpus cavernosum may also affect smooth muscle relaxation in the diabetic corpus cavernosum although addition of indomethacin,

a cyclo-oxygenase inhibitor, had no effect upon the glycated hemoglobin mediated impaired cavernosal muscle response to ACh in rats [17].

Noradrenaline, the principal mediator of smooth muscle contraction within the penis appears to be less abundant in the corpus cavernosum of diabetic men with ED [15] although the responsiveness of smooth muscle to noradrenaline seems to be unaffected [14]. Endothelin-1-induced smooth muscle contraction also appears unaltered in corporal smooth muscle strips of diabetic men with ED [20], though it has been shown that basal concentration of endothelin-1 is increased in men with ED and more so in subjects with diabetes [21].

Advanced glycation end-products (AGEs) that result from non-enzymatic reactions between glucose and lipids, proteins or nucleic acids is found in greater quantity in the corpus cavernosum of diabetic patients. Their covalent bonding with vascular collagen increases vascular permeability, reactive oxygen species, endothelial expression of adhesion molecules and procoagulant expression thus resulting in oxidative cell damage, decreased NO, decreased cGMP and impaired cavernosal smooth muscle relaxation [22].

Structural abnormalities of diabetic penile tissue have also been identified. These include fibrosis of the penile arteries, corpus cavernosum and reduced amounts of cavernous nerve fibers of unmyelinated axons with collagen, factors which will impair smooth muscle relaxation and vasodilatation. Altered gene expression (downregulated mRNA transcript) [23] and increased apoptosis [24] have been noted in penile tissue from diabetic men with ED and rats, respectively.

Neurologic factors

Neuropathy, particularly autonomic neuropathy, has been linked to the development of ED [25], especially under the age of 60 and the principal abnormality appears to be within the parasympathetic nervous system, responsible for achieving tumescence. This is evident from clinical, observational [4,12], and physiologic studies. In some diabetic men, dysfunction of the penile nerves precedes neuropathy in the other peripheral nerves [26]. Abnormalities in deep breathing tests [27], thermal sensation [28], and urinary flow rates [29] that are linked to the integrity of the parasympathetic nervous system are all impaired in diabetic males with ED. By contrast there appears to be no impairment of the sympathetic nervous system [27]. Perhaps surprisingly, despite the clinical link between ED and a symptomatic sensory neuropathy [4], physiological studies undertaken using several different tools have largely shown no difference in sensory innervations between diabetic men with ED and potent males [29,30].

At the cellular level, neurologic changes in diabetic men with ED may be due to hyperglycemia-induced activation of protein kinase C, aldose reductase pathways and non-enzymatic glycation which provokes oxidative stress [31].

Vascular factors

The penis is a highly vascular organ and diabetes may be associated with diffuse atherosclerosis or isolated disease of the external iliac artery [32] both of which may contribute to the development of ED. Observational studies have linked the presence of ED with complications in other microvascular and macrovascular beds of men with diabetes [4,12]. It has been shown that significant ED is associated with diabetic retinopathy severity that is independent of age, duration of diabetes, and cardiovascular risk factors [33], and that ED in diabetic men is associated with proteinuria which is a marker for diabetic nephropathy [34]. Diabetic neuropathy is integrally linked to impaired microvascular blood supply. Abnormalities of vascular function, in particular NO-mediated vasodilatation have been described earlier (see section "Changes within the corpus cavernosum"). Up to 95% of diabetic men with ED show impaired penile blood flow [35] and this has been suggested to be more likely as an etiologic factor in type 1 compared with type 2 diabetic men with ED [36].

Hypogonadism

Hypogonadism is defined as a clinical condition comprising both symptoms with or without signs and biochemical evidence of testosterone deficiency [37]. It was well known that testosterone regulates male sexual behavior and attitudes but it is now more clear that penile erection, and penile blood flow is associated with circulating testosterone levels and experimental studies in humans and animals have shown that testosterone controls several mechanisms (Figure 67.2) that lead to erection and detumescence. The main physiologic action of testosterone appears to be the regulation of timing of the erectile process as a function of sexual desire [38].

The link between diabetes, hypogonadism and ED has become better recognized in the last decade [37–39]. Several cross-sectional studies including those measuring free testosterone levels have shown the prevalence of biochemical and symptomatic hypogonadism in diabetic men from 33–42% [37], justifying the screening for hypogonadism in this population. Though traditionally hypogonadism has been classified into primary (low testosterone, raised gonadotrophins) and secondary hypogonadism (low testosterone, low gonadotrophins), more recently it has become established that hypogonadism with low testosterone and normal gonadotrophins (mixed hypogonadism) can occur. This type is usually associated with obesity and aging but it has been noted in nearly two-thirds of hypogonadal men with T2DM [37]. Visceral obesity and metabolic syndrome can directly impact on testosterone levels and vice versa. Yet, the mechanism of hypogonadism in diabetes is not fully clear. However, a number of mechanisms have been suggested including low circulating levels of plasma sex-hormone-binding globulin causing low total testosterone in diabetes leading to increased insulin resistance, increased aromatase activity resulting in increased conversion of testosterone to estrogen in visceral adipose tissue thereby decreasing testosterone levels, and insulin resistance in T2DM per se leading to reduced insulin action in the hypothalamus resulting in secondary hypogonadism [37–39].
Figure 67.2 The putative role of testosterone in the mechanism of penile flaccidity and erection. (a) Smooth muscle cell contraction in the corpora cavernosa. NE binding to $\alpha 1$ receptors generates IP3, which, by increasing intracellular calcium (Ca2+) levels, activates Ca2+-sensitive CLCAs resulting in membrane depolarization, with the diffusion of the stimulus to the neighboring cells and the opening of VOC. The increased Ca2+ flow promotes, through calmodulin, activation of MLC kinase and cell contraction. Cell contraction is also obtained by altering the Ca2+ sensitivity through a NE-induced activation of a second pathway, rhoA/rOCK, which increases, through a series of kinase activation, the sensitivity of MLC to Ca2+. Testosterone is proposed to negatively regulate this second pathway. (b) Smooth muscle cell relaxation in the corpora cavernosa. NO is generated by NO synthases in either NANC neurons (nNOS) or endothelial cells (eNOS). Both steps are positively regulated by testosterone. NO diffuses into smooth muscle cells and activates an sGC, which in turn transforms GTP into cGMP. cGMP activates PKG, which, through various pathways, ultimately decreases intracellular Ca 2+ levels, leading to relaxation. PDE5 metabolizes cGMP into GMP thereby limiting its effects. This event is positively controlled by testosterone. cGMP, cyclic GMP; CLCA, Ca2+-sensitive chloride channel; CPI-17, protein phosphatase 1 regulatory subunit 14A; eNOS, endothelial nitric oxide synthase; GAP, GTPase activating protein; GEF, guanine nucleotide exchange factor; IP 3, inositol 1,4,5-trisphosphate; MLC, myosin light chain; MLCK, myosin light chain kinase; MLCP myosin light chain phosphatase; NANC, nonadrenergic-noncholinergic; NE, norepinephrine; nNOS, neuronal nitric oxide synthase; NO, nitric oxide; PDE5, phosphodiesterase type 5; PKG, protein kinase G; PLC, phospholipase C; rhoA, ras homolog gene family member A; rOCK, rho-associated, coiled-coil containing protein kinase; sGC, soluble guanylate cyclase; VOC, voltage-operated channels. Other endocrine factors

It is well recognized that hyperprolactinemia, thyrotoxicosis, hypothyroidism or growth hormone deficiency can be associated with the development of ED. There is no significant difference in the circulating levels of these hormones in the diabetic population with and without ED compared with the general population whether examining random measurements or during dynamic testing [40,41]. Whilst mean concentrations of TSH, thyroxine and tri-iodothyronine do not differ in the diabetic and nondiabetic populations who are either potent or have ED, it is recognized that thyroid abnormalities are more commonly observed in diabetes [42].

Drugs

There has been an exponential escalation in the use of polypharmacy regimens in the diabetic individual. Many of these drugs may be associated with the development of ED and it is not surprising that iatrogenic causes of ED may be on the increase. Whilst for many drugs (e.g. antihypertensive agents) the mechanism responsible for the development of ED is clear, for many other drugs the etiologic process is obscure. Although ED is more common in patients on oral hypoglycemic agents or insulin [4], this is more likely to be due to disease duration and hyperglycemia rather than the treatment per se.

Table 67.3 highlights drugs that may be commonly used in treating diabetes and are associated with the development of ED and also drugs used in the general population that commonly precipitate ED.

Psychological factors

There has been a diverse reporting of the prevalence of psychological or psychiatric disease in diabetic men with ED, ranging between 9 and 39% [10,36,43], but it is not possible to categorically implicate these factors as the primary etiologic precipitant of ED. It has been noted that diabetes doubles the chance of depression [44] and there is a strong positive correlation between depressive symptoms and the incidence of ED among diabetic men [45]. It is generally held that organic disease predominates although performance anxiety and other psychological factors [45] that are common in patients with ED (particularly those with other vascular complications) may perpetuate the problem. Libido, the degree of coital, masturbatory and sleep-related erections, and frequency of sexual satisfaction and coital activity is also reduced in diabetic men [46].

Lifestyle factors

There is accumulating evidence linking a number of lifestyle factors, such as sedentary lifestyle, smoking, obesity and alcohol consumption, to the occurrence of ED [47]. Sedentary lifestyle has been shown to be associated with higher prevalence of ED in both diabetic and nondiabetic men [48] with increased physical activity conferring protection upon ED [49]. With the increasing prevalence of obesity and diabetes worldwide and epidemiologic studies indicating obesity as a significant independent risk factor

Table 67.3 Drugs associated with the development of erectile dysfunction in diabetic men

---

Drugs commonly prescribed in the management of diabetes
Cardiovascular protective drugs
Thiazide diuretics and spironolactone
Beta-blockers (propranolol possibly the worst culprit)
Angiotensin-converting enzyme inhibitors
Calcium channel blockers and other antihypertensive agents
Digoxin

Drugs for symptomatic relief of painful peripheral neuritis
Tricyclic antidepressant agents
Carbamazepine
Gabapentin
Nonsteroidal anti-inflammatory agents

Lipid-lowering agents
HMG CoA reductase inhibitors (statin therapy)
Fibrates

Drugs of a general nature commonly associated with development of erectile dysfunction
Alcohol
Anticonvulsant agents
Antiarrhythmic agents
Antipsychotic agents (especially lithium)
Antidepressant agents (tricyclics and monoamine oxidase inhibitors)
Anabolic steroids
Allopurinol
Acetazolamide
Baclofen
Bromocriptine
Cimetidine
Estrogen
Ketoconazole
Metoclopramide
Opiates

---

for ED, a majority of studies have shown that weight loss can improve erectile function in obese men, though the beneficial effect is less profound in obese diabetic men [50]. Whilst it is well known that smoking is a risk factor for ED [47], cessation of cigarette smoking has been shown to improve ED in a considerable proportion of smokers [51].

Other factors

The association between chronic hyperglycemia and ED, and the mechanisms that may be implicated in dysglycemia-induced ED have been discussed. The incidence of ED is increased threefold with an HbA1c level >65 mmol mol^{-1} [52]. It is also recognized that acute deterioration in glycemic control may result in temporary ED in hitherto potent diabetic males although the mechanism is less clearly understood. Painful balanitis is more commonly observed in diabetic males, particularly those with poor glycemic control. Autonomic dysfunction has been suggested as being causative in penile venous leaks, observed in two-thirds of diabetic males with vascular ED [53]. Structural abnormalities of the penis that may cause ED, for example

Peyronie's disease, are no more frequently observed in the diabetic individual compared with the general population.

ED: a marker for cardiovascular disease (CVD)

There are two major hypotheses linking both ED and CVD [16]. One of them implicating endothelial dysfunction and chronic inflammation (seen in both ED and CVD) can be caused by various vascular insults such as diabetes, hypertension, smoking, hyperlipidemia, and hypertension. The pathophysiologic mechanisms of endothelial dysfunction at cellular levels have been described earlier (see section "Changes within the corpus cavernosum"). Chronic low-grade inflammation and oxidative stress may lead to atherosclerosis by contributing to all its stages from the initial phase of increased endothelial permeability through to plaque maturation and rupture [16,54]. Increased levels of markers for inflammation have been demonstrated in both CVD and ED in patients with T2DM [54,55].

The second theory is the artery size hypothesis [16]. Due to the smaller diameter of penile arteries, the same level of plaque burden has a greater effect upon blood flow through the penile arteries compared with coronary and carotid arteries and therefore, ED manifests earlier than CVD.

It has now been shown in clinical trials that ED maybe the early clinical manifestation of generalized vascular disease and is an independent risk for cardiovascular events [16]. It can precede the development of clinically evident coronary artery disease (CAD) by a significant period of time [56,57]. The available data also suggests that the severity of ED correlates with the extent of CAD [58]. Two separate prospective studies have suggested that the risk of new onset CVD was higher in diabetic patients who developed ED and longitudinal studies have shown that ED is able to predict future cardiovascular events [16,57]. Therefore, ED could be a potential marker when screening for silent CAD in diabetic patients.

Management

The clinical assessment and management of ED in the diabetic male is broadly similar to that of ED in nondiabetic men but a few areas are worthy of particular mention. In addition more modern therapeutic approaches are discussed with emphasis on their effectiveness in the diabetic male.

Clinical assessment
History and examination
The presence of other microvascular or macrovascular complications may give a clue to the underlying etiology of ED in a given patient. Conversely, it is extremely important to assess for previously unrecognized cardiovascular disease in diabetic men

with ED, given the strong associations between this triad and the very high prevalence of CVD. Not only may ED precipitate vascular events in some susceptible diabetic men but it is also likely to influence treatment choice.

The International Index of Erectile Function (IIEF) may be used as a guide of the severity of the ED and response to therapy. The IIEF is a 15-item self-administered questionnaire that was developed as a measure to detect treatment-related erectile function in patients in cross-cultural settings. A more abridged five-item version of the IIEF was then developed (IIEF-5) (Table 67.4), which has been shown to possess favorable properties for detecting the presence and severity of ED. A score of ≤21 may be classified as having ED and >21 as not having ED [59].

Investigations
Table 67.5 shows the investigative tools available in clinical practice to assess the etiology of ED in the diabetic male. There is considerable variation worldwide surrounding the extent of routine investigation that should be undertaken and this remains controversial. In our own practice, we restrict investigations to hormonal blood tests although it is recognized that the yield of hitherto unrecognized endocrine abnormalities apart from hypogonadism is low. It is important to screen for hypogonadism as concurrent treatment with both testosterone replacement therapy and PDE5i may be warranted [37]. We avoid extensive investigation unless indicated on a clinical basis since in our experience this rarely influences individual management plans.

Treatment options
General considerations
Weight loss in obese men, increased physical activity, stopping smoking and limiting alcohol consumption to moderate amounts are some important lifestyle changes that need to be reinforced in patients with ED in T2DM [47,60,61]. Sexual activity per se is equivalent to mild to moderate physical activity in the range of 3 to 5 metabolic equivalents (METS; i.e., the equivalent of climbing two flights of stairs) [61]. This is important to understand as reassurance can be given to patients with CAD who are able to achieve this level of exercise without symptoms. Overall it is extremely rare for sexual activity to trigger a cardiac event (30 chances per million per hour in the 2-hour period following sexual activity). The second Princeton consensus guidelines (Table 67.6) have been extremely useful in assessing the cardiovascular risk of a patient in relation to considering treatment for ED [60].

Whilst chronic hyperglycemia is integrally linked to the development of ED there is no evidence that supports restoration of or enhanced erectile performance if glycemic control is improved. However, recently it has been shown in a small group of patients that kidney and pancreas or kidney transplantation alone was associated with improvement in sexual function suggesting that achievement of normoglycemia was paramount in improving sexual function in this group [62]. ED developing

Table 67.4 The five-item version of the International Index of Erectile Function (IIEF-5) questionnaire

Over the past 6 months Score awarded for each item		1	2	3	4	5
Item 1	How do you rate your confidence that you could get and keep an erection?	Very low	Low	Moderate	High	Very high
Item 2	When you had erections with sexual stimulation, how often were your erections hard enough for penetration?	Almost never/never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always/always
Item 3	During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?	Almost never/never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always/always
Item 4	During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?	Extremely difficult	Very difficult	Difficult	Slightly difficult	Not difficult
Item 5	When you attempted sexual intercourse, how often was it satisfactory for you?	Almost never/never	A few times (much less than half the time)	Sometimes (about half the time)	Most times (much more than half the time)	Almost always/always

The IIEF-5 score is the sum of the responses to the five items. The score can range from 5 to 25

Table 67.5 Investigations of erectile dysfunction in diabetic men

Measurements to assess glycemic control (glycated hemoglobin, fructosamine)
Hormone measurements (testosterone axis, prolactin, thyroid function tests, growth hormone, IGF-1)
Prostatic specific antigen measurement
Penile Doppler studies
Responsiveness to a standard intracavernosal injection ("papaverine test")
Physiologic tests of the autonomic nervous system
Detailed psychosexual assessment
Nocturnal penile rigidity studies
Invasive radiologic procedures (cavernosography and arteriography)
MRI pituitary gland

concomitantly with the onset of acute deterioration in glycemic control has a more positive outcome if good glucose control can be re-established. Although diabetic men with ED are commonly taking drugs associated with the development of ED, it is our experience that restoration of potency is usually only successful in those patients where there has been a temporal relationship between the commencement of a drug (within 2 weeks) and the development of ED. Moreover, even if implicated in the etiology, there is often compelling clinical grounds to continue with the drug. The majority of patients will need to consider the therapeutic options summarized in Table 67.7. Figure 67.3 is a useful algorithm to guide physicians in treating diabetic men with ED.

Testosterone replacement therapy in men with hypogonadism

Testosterone replacement in eugonadal men has not been demonstrated to improve erectile performance and has potentially dangerous long-term side effects such as sequelae of resulting polycythemia. In hypogonadal men, testosterone replacement is a successful and relatively fast-acting therapy with recipients often noticing dramatic improvement within days of commencing treatment. Given the short half-life of oral testosterone rendering it ineffective, most authorities consider replacement by other routes. Intramuscular testosterone (typically given every 3 weeks with standard testosterone or every 3 months with longer acting preparations) is well tolerated although painful injection sites may be problematic. Topical preparations including gels, creams, and patches are also popular although practical considerations (avoiding contact with water for a period after application, the presence of sweat on the skin or rashes with the latter) can limit their use. Other less commonly used routes include buccal testosterone, and subcutaneous implants inserted every 4–5 months. Care should be given to assess response (libido and erections) in light of achieving therapeutic replacement levels of testosterone. Other benefits of testosterone may include improved energy levels, muscle bulk and power, cognitive function, mood, and bone density. It is imperative to assess for side effects such as prostatic disease and polycythemia. In men who previously failed to respond to PDE5i and now diagnosed hypogonadal, it has been

Table 67.6 The second Princeton consensus guidelines on cardiovascular risk stratification in patients with sexual dysfunction

Grading of risk	**Cardiovascular status at presentation**	**Recommendation for the management of ED**
Low risk	Controlled hypertension. Asymptomatic and <3 major risk factors for CAD, excluding gender. Mild valvular disease. Mild stable angina. Post MI (>6–8 weeks) or post successful re-vascularization (3–4 weeks). CHF (NYHA class I).	Manage ED within primary care setting. Review treatment options with patient and partner (where possible).
Intermediate risk	Recent MI (between 2–6 weeks). Asymptomatic and ≥3 risk factors for CAD, excluding gender. CHF (NYHA Class II). Noncardiac atherosclerotic sequelae (e.g. CVA). Moderate stable angina.	Specialized evaluation recommended (e.g. exercise testing or echocardiography). Place patient in high or low group depending upon outcome of testing.
High risk	Unstable or refractory angina. Uncontrolled hypertension CHF (NYHA Class III, IV). Recent MI (within last 2 weeks). High-risk arrhythmias. Obstructive hypertrophic cardiomyopathy. Moderate/severe valvular disease.	Refer for specialized cardiac evaluation and management. Treatment for ED to be deferred until cardiac condition stabilized and/or specialist evaluation completed.

Table 67.7 Options used in clinical practice for treating erectile dysfunction in diabetic men

Therapy		**Comment**
First-line treatment	Oral therapy	Phosphodiesterase type 5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil)
	Testosterone replacement therapy	Hypogonadism
Second-line treatment	Intracavernosal therapy	Prostaglandin E1 (alprostadil), thymoxamine, papaverine, phentolamine
	Transurethral therapy	Alprostadil ("MUSE")
	Vacuum tumescence devices	Manual or battery operated
	Psychosexual therapy	Most commonly sensate focusing
Third-line treatment	Penile implants	Usually reserved for men who fail to respond to less invasive measures
Others	Corrective surgery	Peyronie's disease, phimosis, trauma, venous leaks

shown that testosterone replacement therapy subsequently makes patients respond to PDE5i in nearly 60% of cases, underlining the importance of screening for hypogonadism in diabetic men with ED [37–39].

Oral treatment

The biggest single advance in the treatment of diabetic ED has been the development of oral PDE5i. PDE5 is the isoenzyme responsible for the breakdown of cyclic GMP, the final chemical messenger promoting smooth muscle relaxation within the penis. Thus PDE5i facilitates erections through prolonging the availability of cyclic GMP within the corpus cavernosum. Currently there are four commercial forms of PDE5i available, sildenafil [63], vardenafil [64], tadalafil [65], and avanafil [66] (Table 67.8).

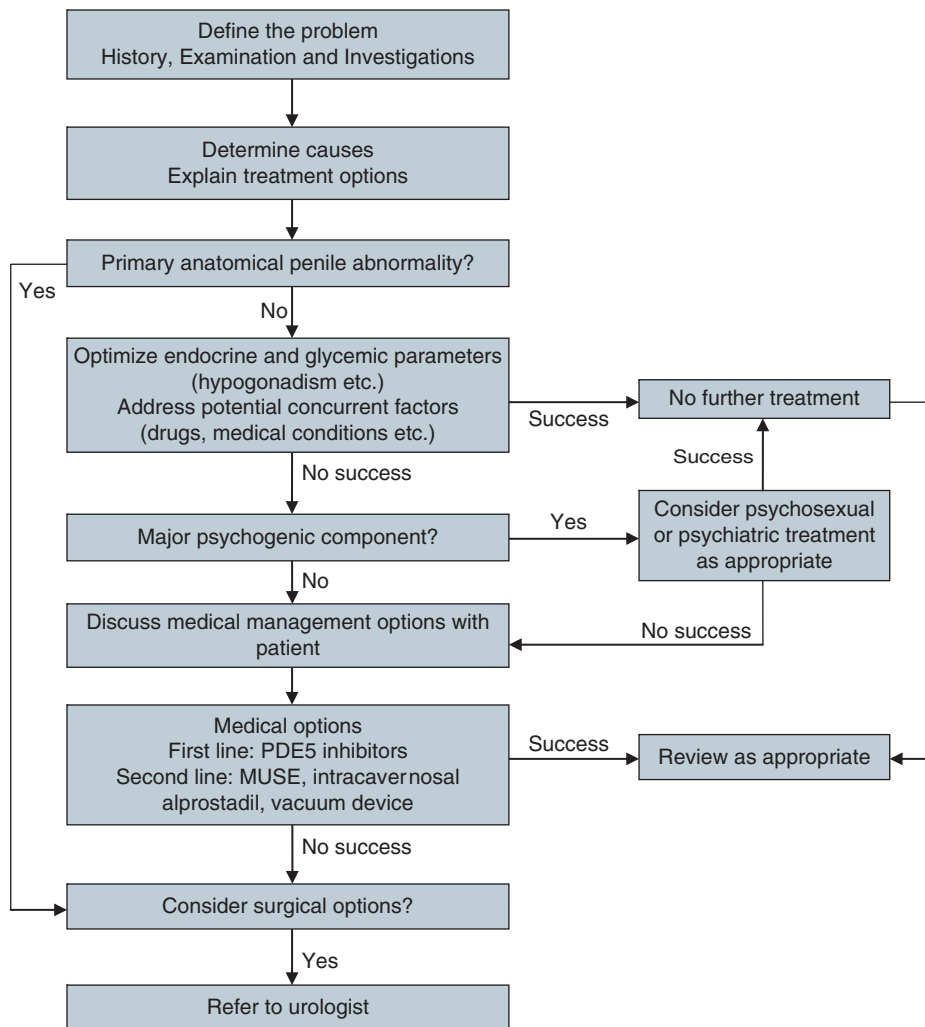
Their effectiveness is in part determined by the severity of ED, the underlying etiology, the clinical characteristics of the diabetic male being treated and the tool used to evaluate response. These factors make it difficult to reliably interpret any clinical differences in effectiveness between these agents. Broadly speaking, however, most clinicians agree that their effectiveness is similar (between 3 and 4 out of 5 patients will respond), a response rate that is less than that of the general population with ED. PDE5i are generally well tolerated with very few patients stopping treatment due to unacceptable side effects. PDE5i have been demonstrated to be a cost-effective approach in the management of ED [67]. Selective CAD patients with stable disease can take PDE5i to treat ED but not when concurrently using nitrates. PDE5i can have positive effects on cardiovascular prognosis and some studies have shown beneficial effect upon


Figure 67.3 Algorithm for treatment for a diabetic man presenting with erectile dysfunction.

endothelial dysfunction and fewer cardiovascular events [57]. However, more robust randomized controlled trials are needed to establish the long-term cardioprotective effects of PDE5i. The use of sublingual apomorphine and oral yohimbine has now ceased since the development of PDE5i.

Several over-the-counter herbal medicines or Chinese traditional medicines have been marketed for the treatment of ED, but there are published studies on humans only for some of them such as *Panax ginseng*, *Butea superba*, and yohimbine, showing efficacy in the treatment of ED but these are not considered robust studies [68–70]. Besides many of these so-called "natural" products contain either potent inhibitors of PDE5 [68] or pharmacologic doses of PDE5i such as sildenafil or tadalafil [70]. This is clearly a concern when marketed freely as it can have potentially fatal interaction with nitrates and therefore improved regulation of natural health products is paramount.

Intracavernosal injections

In the early 1980s, intracavernosal injections with papaverine [71] and phentolamine [72] were reported as being effective in the treatment of ED. There is a high incidence of priapism and other side effects with both drugs and neither have been licensed for this specific indication. Their use has been superseded by a licensed intracavernosal preparation (prostaglandin E1, alprostadil) which can be self-administered directly into the corpus cavernosum (see Figure 67.4). It is the most potent available treatment for ED (approximately 9 out of 10 injections in the general population resulted in successful erections) and has a lower incidence of priapism [73] compared with previous intracavernosal preparations. The occurrence of priapism (erections lasting greater than 6 hours) should be considered a medical emergency and treatment options to facilitate detumescence include leg exercise, locally applied ice-packs, aspiration of blood from the corpus cavernosum

Table 67.8 Comparison of the various PDE5 inhibitors

	Sildenafil	Vardenafil	Tadalafil	Avanafil
Trade name	Viagra®	Levitra®	Cialis®	Stendra™
Dose (mg)	25, 50, 100	5, 10, 20 (film-coated) 10 mg orodispersible	2.5, 5, 10, 20	50, 100, 200
Method of dosing	Usual dose 50 mg, 1 h before sexual activity	Usual dose 10 mg, 1 h before sexual activity	Usual dose 10 mg, either 30 min before sexual activity or 2.5–5 mg daily without regard to timing of sexual activity	Usual dose 100 mg, 30 min before sexual activity
Side effects	Headache, flushing, dyspepsia, visual disturbances and nasal congestion Back pain (more specific to tadalafil)			
Generic contraindications	Concurrent administration with nitrates, nitric oxide donors Extreme caution in patients with previous loss of vision in one eye due to NAION (non-anterior ischemic optic neuropathy)			
Pharmacokinetics				
Onset of action	60 min	60 min	60 min	15–60 min
Duration of action	2–4 h	4–6 h	Up to 36 h	4–5 h
Half-life elimination	3–5 h	4–5 h	15–17.5 h	~5 h
Time to peak action	30–120 min	30–120 min	2–4 h	30–45 min
Bioavailability	~41%	~15%	unknown	unknown
Hepatic impairment (mild to moderate)	Reduce starting dose	Reduce starting dose	No reduction	No reduction
Renal impairment (mild to moderate)	No reduction	No reduction	No reduction	No reduction
Interactions				
Grapefruit juice	May increase drug levels and must be avoided			
Food	High-fat meal can decrease bioavailability	High-fat meal can decrease bioavailability of film-coated tablets	Minimal effect	High-fat meal can decrease bioavailability
Alcohol	Substantial consumption of ethanol may increase the risk of hypotension and orthostasis			

or intracavernosal injection of alpha-adrenergic drugs such as phenylephrine [74]. Corrective surgery is rarely required. Other side-effects include local pain and tingling, bruising, fibrosis, scarring and occasional infection that may limit its use. One of the largest studies of diabetic men with ED has showed that intracavernosal alprostadil was at least as effective in diabetic men compared with the nondiabetic population and no differences in responses were observed between type 1 and type 2 diabetic patients [75].

Transurethral alprostadil

The application of alprostadil in the form of a pellet (see Figure 67.4) (MUSE) in to the urethra has been associated with a 65.9% success rate in achieving erections suitable for sexual intercourse in the general population [76]. Although there are no major prospective diabetes-specific reports of its use, the study mentioned earlier examined a subgroup of diabetic men with ED and reported similar success rates. Penile pain was reported in one third of patients taking this form of alprostadil and other side effects more commonly reported compared with placebo were minor urethral trauma and dizziness although priapism was not reported.

Vacuum devices

Vacuum devices provide a safe alternative strategy to pharmacologic approaches (Figure 67.4). A cylinder with a constriction rubber band at its base is placed over the penis. A manual or battery pump is operated to create a vacuum in the cylinder leading to tumescence. The rubber band is slipped on to the base of the penis and can be left in place for up to 30 minutes. Side effects are rare and include bruising, ejaculatory failure, and penile discomfort. They require a moderate degree of manual dexterity and are usually only suitable for diabetic men in stable relationships. It has been reported that vacuum devices achieve satisfactory erections in nearly 70% of diabetic men [77]. However, nearly 30% of men discontinued use as a result of inadequate rigidity, penile pain, failure to ejaculate, and poor sexual satisfaction.

Psychosexual counseling

Clearly this is the treatment of choice for diabetic men with an overt psychological or psychiatric etiology to their ED. It may also provide an additional approach to patients receiving physical treatment given the performance anxiety seen in many diabetic men with organic ED. There are many different psychological therapies available. One of the most well-known

Figure 67.4 Second-line agents in the treatment of ED (right to left: MUSE, intracavernosal alprostadil, and vacuum device).

forms is sensate focusing employing the Masters and Johnson technique [78]. It requires staged exercises broadly divided into three phases: nongenital, genital, and vaginal containment.

Surgery

Penile prostheses may be considered in diabetic patients who have failed to respond to less invasive measures. There are various complexities of prostheses which range from simple malleable devices that produce a permanent semi-rigid erection to more complex inflatable devices which are associated with an implanted reservoir system enabling tumescence or detumescence as required. Mechanical failure is relatively common, particularly with the inflatable devices. Also extrusion of the prosthesis, pain and bruising may occur, but in centers with good experience of inserting these devices, these complications are rare [79].

Corrective surgery may be considered in patients with primary penile abnormalities such as Peyronie's disease and venous ligation may be undertaken in diabetic patients with established venous leaks. In diabetic patients with impaired penile blood flow, microvascular surgical techniques have proved disappointing and are rarely performed.

Future treatment options

Topical agents either as monotherapy (nitrates) or combination therapy (e.g. aminophylline, isosorbide dinitrates and co-dergocrine [80]) applied to the penis continue to be explored as do other oral agents such as L-arginine. Phase IIb trials with bremelanotide (a synthetic peptide analogue of α-melanocyte stimulating hormone) have demonstrated efficacy in diabetic men but its challenging adverse effect profile (nausea, emesis, and increased blood pressure) may preclude development of this drug for the treatment of ED [81]. The effectiveness of other intracavernosal agents, for example VIP, are also being evaluated. Although controversial, gene therapy through introduction of vectors that promote the synthesis of nitric oxide synthase (responsible for the production of NO) have been shown to be effective in promoting erections in diabetic rats [82]. Novel treatments such as umbilical stem cell therapy have shown promise in ED (for men with T2DM) and may become available in the future for refractory cases [83].

Conclusions

In the 1980s it was common for diabetic patients with ED to suffer in silence. Both patients and healthcare professionals avoided discussing the subject and treatment options were not known about, services to provide treatment were scanty and successful therapeutic treatments were mainly unlicensed and poorly tolerated. Today, many healthcare professionals involved in diabetes care adopt a holistic approach and can successfully treat ED within their own service without the need for referral to specialist services. Previously, the common approach of ushering diabetic patients with ED out of the consultation room with no treatment other than being told "not to worry, it will get better with time" should no longer occur.

Periodontal disease and diabetes mellitus

Wenche S. Borgnakke[1] and Robert J. Genco[2]

[1]Department of Periodontics and Oral Medicine, University of Michigan School of Dentistry, Ann Arbor, MI, USA

[2]Department of Oral Biology, State University of New York School of Dental Medicine, Buffalo, NY, USA

Key points

- Periodontal diseases are common globally with up to 90% affected by the reversible form, gingivitis, and around half of adults having moderate or severe periodontitis with irreversible loss of soft and hard tissues surrounding the teeth.

- Periodontitis increases glycemic level and contributes to hyperglycemia/prediabetes, incident type 2 diabetes, diabetes complications, and possibly gestational diabetes.

- Periodontal treatment improves the glycated hemoglobin level by about 0.4 percentage points, similar to adding a second oral diabetes drug to metformin.

- Periodontitis and uncontrolled/poorly controlled diabetes adversely affect each other.

- Individuals with diabetes are more prone to periodontitis, and extent and severity of periodontitis increases with increasing levels of hyperglycemia. Therefore, periodontitis was suggested as the "sixth complication of diabetes" 20 years ago.

- People with diabetes have lost more teeth than those without diabetes.

- People with diabetes who obtain dental cleanings incur lower costs for diabetes-related medical care, including inpatient, outpatient, laboratory, and pharmacy costs.

- To manage diabetes, it would be beneficial to patients and society for healthcare providers to collaborate in patient-centered teams that include dental professionals.

Introduction

Periodontal disease

The vast majority of the world's population are affected by periodontal disease with estimates of up to about 90% when the reversible form, gingivitis, is included [1]. The Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) is the only comprehensive effort to estimate summary measures of global population health by cause, providing comparable estimates of the burden of 291 diseases and injuries in 1990, 2005, and 2010 [2]. Oral conditions affect 3.9 billion people, and untreated caries in permanent teeth is the most prevalent condition evaluated by GDB, with a global prevalence of 35% for all ages combined. During the 20 years from 1990 to 2010, the number of years lived with disability (YLD) increased for periodontal disease by 57.3%, whereas YLD for edentulism decreased by 12.4% [3]. This is in accord with people living longer and also keeping their teeth into older age. In 2010, severe periodontitis came in at sixth place of the most common diseases in the world, after dental caries of permanent teeth (1st), tension-type headache (2nd), migraine (3rd), fungal skin diseases (4th), and other skin and subcutaneous diseases (5th). The estimated 2010 global prevalence of the most severe category of periodontitis was just over 10% (10.79%), affecting men (10.89%) and women (10.68%) equally [2,3].

This estimate agrees with the analysis of the most recent national, representative data collected in the United States (US) during the 2009 and 2010 waves of the National Health and Nutrition Examination Surveys (NHANES). It estimates that about half the population aged 30 years or older have some form of periodontitis, either mild (~10%), moderate (~30%), or severe (~10%) [4]. Furthermore, 45% the US population 45–64 years old and 60% of 65–74 year olds have moderate or severe periodontitis with variation between race/ethnic groups [5].

For example, among Puerto Ricans 70 years and older, 83% have moderate (50%) or severe (24%) periodontitis [6]. Even in developed countries with a high standard of living, periodontal disease is prevalent. For instance, in a random sample of 1115 Danish 35–44 and 65–74 year olds, only 7.7% and 2.4%, respectively, had healthy periodontal conditions [7].

In susceptible individuals, periodontitis will progress with increasing loss of the soft and hard tissues surrounding the tooth. Unfortunately, this process may occur without any noticeable signs and symptoms. In the absence of any periodontal

treatment, loosening of the teeth may occur and the ultimate consequence would be their loss.

Diabetes

Worldwide, an estimated 382 million (8.3%) people currently have diabetes mellitus, with almost half of them (175 million) undiagnosed. Another 316 million with impaired glucose tolerance (IGT) are at risk. By 2035, the global population with diabetes is projected to rise by 55% to 592 million with another 471 having IGT, totaling 1 billion people. These are the ominous 2013 estimates by the International Diabetes Federation [8]. About 80% of persons with diabetes live in low- and middle-income countries, and in any country, the socially disadvantaged are most prone to suffer from this disease. Rapid lifestyle changes are bringing obesity and T2DM to historically high levels in countries in the Middle East, Western Pacific, sub-Saharan Africa, and South-East Asia. The highest numbers of people with diabetes live in China (98.4 million), India (65.1 million), and the USA (24.4 million) [8], with the latter estimate updated to 29.1 million, including 8.1 million undiagnosed in the US alone [9]. Global health expenditures due to diabetes for people 20–79 years of age are estimated for 2013 at USD 548 billion and for 2035 at USD 627 billion [8]. According to The World Health Organization (WHO), more than 80% of diabetes deaths occur in low- and middle-income countries, and diabetes will be the seventh leading cause of death in 2030 [10]. Based on health examination surveys and epidemiologic studies conducted from 1980 through 2008 among 2.7 million participants 25 years and older in 199 countries and territories, glycemia and diabetes were found to be rising globally, driven by both population growth and aging and by increasing age-specific prevalences [11].

Periodontal disease and diabetes are common, chronic, multifactorial diseases that share many risk factors [12]. The prevalence of both increases sharply with age and they often occur in the same individuals. Longevity is increasing in most countries and there is a tendency for people to keep their teeth longer than in the past. Hence, the need for treatment of both diseases, especially in older age groups, is also increasing and will likely continue to do so. About two-thirds of the US population 65 years and older have periodontitis [4] and more than one-quarter (25.9%) of this age group have diabetes [9].

Only recently are we beginning to unravel the mechanisms underlying both diseases and their mutual relationship and hence it is necessary to improve our understanding of their complex interactions. Currently, it is likely that a major mechanism in this relationship is the systemic inflammatory response. Understanding the association between periodontal infection and diabetes has increased dramatically in recent years, as illustrated by the surge in the number of citations in PubMed over the last decade (Figure 68.1). Interprofessional management of the individuals with these chronic diseases should be our goal. Through creating a patient-centered medical home for each individual, proper management could benefit all involved.

Periodontal diseases: assessment

In the clinical situation, many factors will play a role in the decision made mutually by the dental professional and the patient regarding any treatment and management of gingivitis and periodontitis. Unfortunately, periodontitis is usually symptom free in the early and intermediate stages. Most people in the world have gingivitis at one or more sites in the mouth, but only some will experience bleeding during tooth brushing, flossing, or mastication of hard food items. Not until considerable breakdown of bone manifests itself as migration (turning, tilting, moving) or loosening of the tooth (mobility)—or suppuration causing observable flow or bad taste—will the patient become aware of the disease. At that time, it is often too late to salvage the tooth. In addition to observable signs and symptoms, patient-specific factors will be taken into account when a treatment plan is developed. Such factors include age, education, comprehension, ability and willingness to practice effective oral hygiene, frequency of check-up visits, personal values placed on oral health and teeth, as well as financial issues of payment and insurance coverage.

Figure 68.2 illustrates clinical measurement of various attributes of the periodontal tissues [13]. Color (reddening) or spontaneous bleeding in the gingival tissues, tooth mobility, or suppuration are often recorded. A common measure is bleeding upon probing (BOP), either tooth, surface, or site based, and a score can be allocated to each tooth, each tooth surface, or at each site that was probed for periodontal pocket depth. Complicating matters is that periodontitis, that is, irreversible breakdown of periodontal soft and hard tissues, occurs in very limited areas. The standard is probing at six different sites around each tooth. Periodontitis is site specific, which means that measurements just millimeters apart can yield substantially different results. Therefore, it is crucial to measure several sites for each surface [14]. Because the breakdown does not occur evenly or predictably on teeth, tooth surfaces, or sites on each surface, it is difficult to create valid and reliable statistical weights that can account for such variation when only a few sites in the entire dentition are measured for time and convenience reasons.

Assessment of periodontal disease may also be based on radiographic examination of the entire dentition at once (panorama radiograph), of segments of the dentition (bitewing radiographs), or of individual teeth (periapical radiograph that also shows the tip of the root and its adjacent jawbone). Due to the chronic nature of bone breakdown, it is not possible to determine whether the disease is active, based on radiographic measures at one time point, which could represent past bone loss. Assessment of antibodies as well as DNA identification of certain bacteria most often associated with periodontitis in saliva or serum may also be used, but these tests have not been validated.

Unfortunately, there are no detailed diagnosis codes in most countries for the two most common oral diseases, namely dental caries and periodontal diseases. Instead, codes for services provided are subsequently interpreted as an underlying
Figure 68.1 Number of PubMed citations on periodontal disease and diabetes by publication year: about half of the 2278 papers were published the last 8 years.

diagnosis for a condition in need of treatment having been present prior to the treatment rendered. Moreover, most countries do not have centralized databases for oral health. Consequently, it is very difficult to track or estimate the prevalence and trends in dental diseases in most populations.

To complicate matters, the resources needed to conduct population-based studies, or even large-scale clinical periodontal examinations, are time consuming and expensive. Properly trained and calibrated dental professional examiners and persons to record the measurements or codes called out (or alternatively voice-recognition devices) are required.

Additionally, a portable examination chair or other seating, good lighting, sterile (disposable) instruments, and various disposables are needed. It would be unethical to withhold information from the examinees regarding any significant findings for which effective treatment is known to exist, so referrals would often be made. In order for the researchers to conduct meaningful statistical analyses later, responses to a written questionnaire or to an oral interview are needed to determine age, sex, socioeconomic level, medical history, and use of medications (for instance, those that influence inflammation such as statins and omega-3). In addition, responses

regarding professional and home dental care, medical care, diet and exercise, and habits such as smoking and snuff use are required. Moreover, a brief physical examination is necessary to obtain data on weight, height, waist circumference, blood pressure, and glucose or glycated hemoglobin.

Such examination can easily last an hour or more per person, depending on the number of teeth and the extent of measures of various aspects of periodontal diseases. Further complicating matters is the fact that there are currently no globally accepted, standard case definitions for surveillance of periodontal diseases. Consequently, studies are not directly comparable; many research groups determine what will be considered periodontal disease in their specific study. The following example will illustrate this important, basic point, which is often not

sufficiently emphasized. In 1296 pregnant women, Manau and colleagues collected data on dental plaque, BOP, periodontal probing depth, and clinical periodontal attachment loss [15]. To this data set, they applied 14 different, previously published case definitions for periodontal disease, using over 50 continuous variables. The result was that between 3.2% and 70.8% (mean 35.8($\pm$21.6)%, median 29.7%) of these women had periodontal disease, depending on which of the 14 case definitions was used.

However, recent case definitions developed for surveillance of periodontal disease by a joint workgroup of Centers for Disease Control and Prevention (CDC) and the American Academy for Periodontology (AAP) are used globally and are increasingly regarded as the standards [16,17]. Application of identical case definitions in different groups, populations, and countries would greatly enhance the comparability of findings on prevalence. In addition, this would enable estimation of trends within each population studied.

The lack of uniformly used definitions and attention to exactly how periodontal disease is defined must be kept in mind when interpreting results of studies related to periodontitis, including the evidence for the bidirectional effects of periodontitis and diabetes.

Self-reported periodontal disease

Of great interest and importance to healthcare providers, policy makers, administrators, and epidemiologists alike is the search for more economical modes of assessment of both individual and population-based risk for periodontal disease. There is increasing evidence for the validity and reliability of estimation of risk for periodontitis using self-report [18]; that is, using responses collected by simply asking individuals some questions that are shown to associate with the actual clinical status. Based on a pool of items formerly validated in population studies, the joint CDC/AAP workgroup has developed, cognitively tested, and applied in the field in Australia and the USA a set of eight such questions in English and Spanish [19,20]. In the 2009 and 2010 waves of NHANES, two important developments occurred in people 30 years and older for the first time ever: (1) all 28 teeth (excluding third molars) were clinically periodontally examined at six sites each (vs. formerly half-mouth, two or three sites per tooth), and (2) the eight CDC/AAP self-report questions regarding periodontitis were included in the questionnaire. The responses were obtained during in-home interviews with greater than 95% response rates and later validated against full-mouth clinically assessed periodontitis in 3743 adults. The self-reported measures performed well in predicting periodontitis in US adults. Furthermore, the questions and their answers achieved good results in predicting both the absence of any periodontitis and the presence of various levels of periodontitis [20]. The eight questions concern gum health and gum treatment history, loose teeth, bone loss around teeth, tooth not looking right, and use of dental floss and mouthwash. Table 68.1 displays these questions. It should be noted that the items are not yet ready for direct use in clinical practice to predict the risk for periodontitis in individuals, because such an index would require allocating weights to the item responses and demographic information, as well as field-testing and validation. However, the questions may be useful in assessing population-based levels of disease once validated in populations other than the US or Australian populations already tested [20,21].

Periodontal diseases and inflammation: localized and generalized

The two most common periodontal diseases are gingivitis, a reversible infection of the gingival tissues that surround the tooth, and periodontitis that is a multifactorial permanent breakdown of the supporting soft and hard tissues around the tooth. Both diseases are initiated by the microbial biofilm that accumulates on the tooth. Since the tooth consists of the only non-shedding tissue in humans, the biofilm can persist and organize itself over an extended period of time, provided external forces, such as tooth brushing or flossing do not disturb the dental plaque.

Whether the responding inflammation progresses to periodontitis depends on a multitude of factors mostly determined by the host [22]. Hence, periodontitis develops most often in susceptible individuals, and is not yet able to be predicted. Therefore, periodontitis can be regarded as an indication that the patient may have systemic conditions and diseases that deserve scrutiny and possibly referral for medical assessment and treatment [23].

The microbial biofilm will cause infection and local inflammation in the gingival tissues. The accompanying swelling will provide deepened spaces, so-called periodontal pockets, around the tooth, which will enhance the overgrowth of the biofilm. With progressing infection, the local inflammatory response escalates into cascading systemic responses during which the inflammatory mediators are disseminated throughout the body. Some of the commensal anaerobic bacteria will easily penetrate the inflamed tissue and enter the systemic circulation, in which they may be carried by phagocytic cells. Some of these bacteria and their endotoxins (lipopolysaccharides) further exacerbate the systemic anti-inflammatory processes. Wherever these bacteria lodge themselves, they may be able to invade and multiply, colonizing tissues and organs at body sites remote from the oral cavity. The subsequent local effect further adds to the systemic cascades of inflammatory responses.

This inflammatory response contributes to insulin resistance with elevation of blood glucose levels. Periodontal infection contributes to the cumulative burden of infection and its subsequent inflammatory responses. This is the main mechanism thought to underpin the effect of periodontal disease and systemic diseases, including diabetes and cardiovascular diseases. It has been shown that periodontitis can also contribute to development of prediabetes and T2DM—even possibly gestational diabetes.

Table 68.1 CDC/AAP* questions for self-reported periodontal disease used in NHANES 2009 and 2010

NHANES Item Name: Item Verbatim in English and *Spanish (Italicized)* (Response Categories)

OHQB010: Do you think you might have gum disease?
¿Piensa usted que tal vez sufra de la enfermedad de las encías?
(Yes, No, Refused, Don't Know)

OHQB020: Overall, how would you rate the health of your teeth and gums?
En general, ¿cómo diría que es el estado de salud de sus dientes y encías?
(Excellent, Very good, Good, Fair, Poor, Refused, Don't Know)

OHQB030: Have you ever had treatment for gum disease such as scaling and root planing, sometimes called "deep cleaning?"
¿Alguna vez ha tenido usted tratamiento de las encías tipo raspado o alisado de las raíces, que a veces se conoce como "limpieza profunda"?
(Yes, No, Refused, Don't Know)

OHQB040: Have you ever had any teeth become loose on their own, without an injury?
¿Alguna vez se le ha aflojado algún diente por sí solo sin haber tenido una lesión?
(Yes, No, Refused, Don't Know)

OHQB050: Have you ever been told by a dental professional that you lost bone around your teeth?
¿Alguna vez le ha dicho un profesional de la salud dental que usted ha perdido hueso alrededor de los dientes? (Yes, No, Refused, Don't Know)

OHQB060: During the past three months, have you noticed a tooth that doesn't look right?
En los últimos tres meses, ¿ha notado usted un diente que no parece verse bien?
(Yes, No, Refused, Don't Know)

OHQB070: Aside from brushing your teeth with a toothbrush, in the last seven days, how many times did you use dental floss or any other device to clean between your teeth?
Aparte del cepillado de sus dientes, ¿cuántas veces ha usado la seda/hilo dental o algún otro medio o utensilio para limpiarse entre los dientes en los últimos siete días?

Conceptual model of pathways linking periodontitis to diabetes

Figure 68.3 illustrates conceptually the main pathways in which periodontal inflammation contributes to diabetes and glycemic control, including hyperglycemia in people without diabetes or with prediabetes [24,25]. Periodontitis represents a chronic infection that contributes to the local and systemic cumulative bacterial burden. The inflammatory responses by the host to this periodontal infection are likewise chronic and manifest themselves as low-grade inflammation that maintains a role as a source for proinflammatory cytokines, such as interleukin-6 (Il-6), tumor necrosis factor-alpha (TNF-α), and interleukin-1-beta (Il-1β). These and other inflammatory mediators play important roles in the pathogenesis of insulin resistance by disrupting insulin-signaling leading to reduced uptake of glucose by the cells. Periodontal infection also leads to secretion by the liver of acute-phase reactants, such as C-reactive protein (CRP), fibrinogen, and plasminogen activator inhibitor-1 (PAI-1). The reactants in turn contribute to insulin resistance leading to hyperglycemia and prediabetes,

and ultimately manifest T2DM. Epidemiologic studies have identified these acute-phase reactants as risk indicators and risk factors for the prevalence and incidence of both atherosclerotic cardiovascular disease and diabetes. Being a component of the metabolic syndrome, insulin resistance is recognized as a risk factor in the pathogenesis of diabetes and its complications, as well as cardiovascular disease. Adipokines and various other factors that contribute to insulin resistance are clearly important but are omitted from this model for simplicity of presentation.

Periodontal disease and diabetes mellitus: a two-way relationship

Periodontitis and poorly controlled diabetes negatively influence each other in a two-way causal relationship. Twenty years ago, periodontitis was suggested as the sixth complication of diabetes [26], and ample evidence now exists to show that periodontitis is indeed a nonspecific infectious complication of poorly- or un-controlled diabetes. The first systematic review
Figure 68.3 Conceptual model integrating the clinical pictures of periodontitis and obesity with the hypothesized role of inflammation in the pathogenesis of diabetes and poor glycemic control. Inspired by Donahue and Wu 2001 [25]. Source: Taylor et al. 2010 [24]. Reproduced with permission of Colgate-Palmolive Company.

of the evidence for the opposite effect—namely, the effect of periodontal disease on hyperglycemia, prediabetes, diabetes, and diabetes complications—was published in 2013 [27,28].

Until recently, we believed that people with diabetes in general were more prone to periodontal disease, based on the view that individuals with diabetes have a compromised immune system and hence are less able to fight infecctions. However, only poorly or uncontrolled diabetes causes periodontal problems. A large number of studies have addressed this issue (Figure 68.1) and there is now a better understanding of the association between periodontal disease and diabetes. Examples of studies of different designs will be described to provide a summary of the depth and breadth of the body of evidence for the reciprocal relationship between periodontitis and diabetes.

Oral-systemic evidence reviewed by experts from Europe and the USA

Reports from a joint workshop comprising experts from the European Federation of Periodontology (EFP) and the American Academy of Periodontology (AAP) assessed the current scientific evidence for associations between periodontal disease and diabetes, cardiovascular disease, adverse pregnancy outcomes, and other systemic diseases. These reports may be freely accessed at: http://onlinelibrary.wiley.com/doi/10.1111/jcpe.2013.40.issue-s14/issuetoc?dmmsmid=73654&dmmspid=17129767&dmmsuid=1955451 (last accessed July 15, 2014). Four of these reports concern diabetes, namely three peer-reviewed reviews on underlying pathologic mechanisms [29,30], effect of periodontal treatment on glycemic control [31,32], and effect of periodontal disease on diabetes [27,28]. The fourth is a consensus statement summarizing the evidence regarding

periodontal disease and diabetes [33,34]. It also contains recommendations regarding oral healthcare in people with diabetes, which will be described at the end of this chapter. Additionally, the results of the systematic review of epidemiologic observational evidence for the effect of periodontal disease on diabetes [27,28] are summarized in a publicly accessible webcast at: http://www.scivee.tv/node/58235 (last accessed July 15, 2014).

Longitudinal studies from which causality may be deducted are rare. Evidence regarding causal relationships between periodontal disease and diabetes stems mostly from longitudinal clinical, serologic, and radiologic studies among the Pima Indians in Southwestern USA. These Native Americans have an extraordinary high prevalence of T2DM. The studies showed in this population with poorly controlled diabetes and poorly managed periodontal disease that T2DM was associated with highly increased risks for periodontal disease. However, only recently has it become evident that it is not having a diagnosis of diabetes mellitus *per se* that causes increased prevalence and severity of periodontitis, it is the hyperglycemia in un- or poorly controlled diabetes that most likely is the offender [12].

The fact that individuals with well-controlled diabetes are not at greatly elevated risk for periodontal disease is demonstrated in several epidemiologic observational and interventional studies. For example, among 4343 NHANES 1988–1994 participants aged 45 years and older of whom 502 had diabetes (fasting plasma glucose $\geq 126 \, \text{mg dL}^{-1}$), severe periodontitis was found in 14.3% of those with poorly controlled diabetes (HbA1c > 9%) and in 8.8% of those with "better" controlled (HbA1c ≤ 9%) diabetes, compared to 4.1% among people without diabetes [35]. After controlling for potential confounders, individuals with diabetes who had poor glycemic control had 2.90 times, and those with better control 1.56 times, higher risk for periodontitis than individuals without diabetes. Only the former obtained statistical significance. These findings support the notion that individuals with well-controlled diabetes have about the same prevalence of periodontitis as otherwise similar individuals without diabetes, when keeping in mind that the threshold for "good" diabetes control currently would likely be lower than the 9% HbA1c used in this report [35]. Furthermore, persons with well-controlled diabetes usually respond well periodontally to routine, nonsurgical periodontal treatment.

Effect of diabetes on periodontal disease

In the studies among Pima Indians, the age of onset, severity, and prevalence of periodontal disease are all adversely affected by T2DM [36,37]. In fact, individuals with diabetes were up to four times more likely to develop periodontal disease than their counterparts without diabetes [38]. These studies confirmed and extended a 20-year-old landmark study in a Finnish population that showed that poorly controlled diabetes increases the risk for progressive periodontal bone loss more than diabetes under good glycemic control does [39].

A large-scale epidemiologic survey in Germany assessed multiple potential risk factors and supports the associations between both T1 and T2DM and periodontitis [40].

People with diabetes have more periodontal disease, according to a 2009 systematic review and meta-analysis of 49 cross-sectional studies by Chavarry and colleagues [41]. Of these studies, 17 concerned type 1; 26 type 2; and 6 both T1 and T2DM. In another review of cross-sectional studies worldwide that included a control or comparison group without diabetes, the prevalence of periodontal disease was higher in the diabetes groups in the vast majority of the respective studies [24].

A dose–response relationship was demonstrated in a study of both T1DM and T2DM and periodontal disease in Columbia [42]. The higher the level of hyperglycemia, the more severe was the periodontitis. In a study of T1DM, more children and adolescent with diabetes had periodontal disease as compared to those with no diabetes OR = 2.24 (1.02–4.93) [43].

About one third of the US adult population with diabetes have moderate or severe periodontal disease with young adults being about twice as likely — and those 45 years and older almost three times as likely — as their peers without diabetes to have severe periodontitis [44].

The Chavarry 2009 systematic review and meta-analysis mentioned earlier included eight longitudinal studies, namely four observational and four interventional studies among participants with T1DM and T2DM [41]. The authors conclude that T2DM is an independent risk factor for periodontitis.

In the large, longitudinal population based study of 2558 participants between 20 and 81 years of age in Western Pomerania in northern Germany, the progression of periodontitis was monitored over a period of 5 years [45]. Importantly, diabetes was demonstrated to be a significant risk factor for incident clinical attachment loss as well as increased periodontal probing depth. The following other risk factors were identified: male sex, age 65 and older, low education level, and being single or divorced. Hence, the authors urge offering periodontal prophylaxes or maintenance sessions especially targeted to those groups who experienced the greatest progression of periodontitis.

Type 1 diabetes

Children who are between 6 and 14 years old have a mixed dentition, that is, both primary teeth (baby teeth) and permanent teeth in various stages of eruption are present in the oral cavity. Studying 270 such children with diabetes and comparing them to 320 children without diabetes, it was shown that the former exhibited accelerated tooth eruption in the late mixed dentition period at ages 10–14 [46].

In an earlier study including 142 patients 11 to 18 years of age with T1DM, it was found that 9.8% suffered from periodontitis, as compared to 1.7% of a comparable control group of 116 subjects with no diabetes [47]. Another study was conducted among 18–50-year-old patients in India with T1DM for at least 4 years and compared them to healthy controls matched for age, physical build, and oral hygiene [48]. The mean HbA1c

level was 8.8% in the diabetes group. It was demonstrated that all periodontal disease measures (gingival bleeding, periodontal probing depth, and clinical attachment loss) were more severe in T1DM patients, despite currently having similar oral hygiene levels. Periodontal destruction assessed as mean clinical attachment level was also greatly worse in subjects with longer disease course (4.1 vs. 2.8 mm), poorer metabolic control (4.4 vs. 2.2 mm), and the diabetes complications retinopathy, neuropathy, and nephropathy (4.2 vs. 2.3 mm).

Lalla and colleagues demonstrated that periodontal breakdown can begin very early in life in children and adolescents with diabetes [49,50], and gingival bleeding is more common in children with diabetes compared to those without diabetes [51]. Furthermore, this accelerated periodontal destruction in children is related to metabolic control. Hence, it is likely important to attain and maintain good glycemic control to minimize periodontal disease, just as is the case for other diabetes complications [52].

Effect of diabetes intervention on periodontitis in type 2 diabetes

One recent report investigated the reverse effect, that is, the effect of interventions to improve glycemic control on the periodontal disease in persons with T2DM. This is a novel concept to be studied. In Tokyo, 35 persons between 40 and 75 years and HbA1c of at least 7.4% and with periodontitis underwent therapy to improve glycemic control — without periodontal treatment. Glycated hemoglobin (HbA1c), high-sensitivity C-reactive protein (hsCRP), and periodontal measures were assessed at baseline, and 2 and 6 months after the therapy to improve glycemic control. The authors concluded that effective glycemic control improves periodontal bleeding on probing in people with T2DM [53].

Effect of periodontal disease on diabetes

Evidence from cross-sectional studies clearly shows that individuals with periodontitis, especially if severe and of great extent, have much higher risks for elevated blood glucose or glycated hemoglobin than those with a healthy periodontium. However, such evidence is able to show only associations, but not temporality. In early 2013, the first systematic review of epidemiologic, nonexperimental, observational evidence for the effect of periodontal disease on hyperglycemia, prediabetes, and diabetes was published [27,28]. The systematic review only considered studies in which the temporal sequence of the effect of periodontitis on glycemic control could be assessed and hence included mostly longitudinal studies. However, studies on diabetes complications were also included because such complications are not known to cause periodontal disease and therefore, the temporal sequence was given. Seventeen studies were analyzed and

they support significant, adverse effects of periodontal disease on glycemic control, diabetes complications, and development of type 2 (and possibly gestational) diabetes. Importantly, periodontal disease seems to lead to elevated glucose levels even in healthy individuals free of diabetes. Major limitations were: small studies, variability of exposure and outcome parameters, and limited generalizability of the results [27,28].

The notion that periodontal infection would adversely affect blood glucose levels is biologically plausible, as this is a normal part of the inflammatory response to infection as it occurs anywhere in the body. Periodontal infection likely contributes to the cumulative burden of infection and its subsequent systemic inflammatory response. Moreover, periodontal infection leads to systemic dissemination of members of the oral microbiome. Several of these microorganisms and their endotoxins induce strong systemic inflammatory responses in susceptible individuals, which in turn contribute to insulin resistance. It was demonstrated in a longitudinal study of 3280 participants free of diabetes and obesity at baseline, that individuals who later developed diabetes indeed had higher levels of bacterial DNA in their blood than those who did not develop diabetes [54]. The source and role of these bacteria are not known, but they may originate from the oral, gut, or skin microbiomes.

To further strengthen the evidence for the effect of periodontal infection on development and control of diabetes and its complications, observational cohort studies are needed in larger populations for longer periods. In addition, intervention studies in which baseline HbA1c is elevated (uncontrolled glycemic levels) should demonstrate that periodontal treatment is effective in reducing systemic inflammation to finally establish that periodontal treatment that reduces the periodontal infection will also reduce HbA1c levels.

Effect of periodontal treatment on diabetes

Because periodontal infection contributes to the cumulative infection burden and its associated inflammatory responses, it should logically follow that elimination — or prompting a major decrease of the infectious burden — should lead to a decrease in blood glucose levels.

Increasingly solid evidence is emerging for routine, nonsurgical periodontal treatment leading to significant decrease in glycated hemoglobin at 3 months post treatment, and Table 68.2 displays all such meta-analyses conducted. The resulting decrease of between 0.4% and 0.8% HbA1c actual difference is not only statistically significant, but also clinically relevant in diabetes management. The magnitude of this improvement upon periodontal treatment is comparable to that seen by adding a second oral antidiabetic medication to metformin [33,34]. It is noteworthy that these meta-analyses include a 2010 review by the Cochrane Collaboration [55] and that they all come to largely the same conclusion.

The effects of periodontal therapy on HbA1c levels in patients with poorly controlled diabetes are illustrated in Table 68.3, which displays detailed (unpublished) data from the three

groups receiving active treatment in the first such study by Grossi and colleagues in 1997 [56]. Treatment consisted of extraction of so-called hopeless teeth (unsalvageable due to periodontal disease), root planing, and ultrasonic scaling, supplemented with 160 mg doxycycline twice daily for 14 days. Patients whose baseline HbA1c was 7.9% or less experienced a reduction of HbA1c level that was not statistically significant, whereas individuals whose baseline HbA1c was 8.0% or greater showed statistically significant reductions at 3 months post intervention (Table 68.3). It is therefore reasonable to expect a greater reduction in glycated hemoglobin after periodontal therapy in patients whose initial HbA1c level is high.

These results are clinically significant as well. The CDC estimates that "in general, every percentage point drop in A1c blood test results (e.g. from 8.0% to 7.0%) can reduce the risk of microvascular complications (eye, kidney, and nerve diseases) by 40%" [44].

Effect of periodontal disease on diabetes complications

The relationship between periodontal disease and other complications of diabetes has been addressed by several studies. In individuals with T1DM and T2DM, those without teeth or with periodontal disease, especially severe disease, have higher risk for diabetes-related complications than those without or with little periodontal disease [23,27,28,57,58]. A dose–response effect seems to exist between severity of periodontal disease and risk for complications. For instance, it was found that individuals with diabetes suffered from periodontitis that was more severe if they also experienced other complications, such as retinopathy [59]. Assessment of microvascular hemorrhaging at two distinct anatomical sites was conducted only in the 1988–1994 NHANES [60]. From this study it was found that individuals with bleeding in one or more of five gingival

sites had a 57% increased odds ratio for also having retinal hemorrhaging. Modeling showed that 51% of this association was explained by degree of hyperglycemia, assessed by HbA1c levels. A Japanese study also reported the severity of periodontal disease was significantly correlated with the severity of diabetic retinopathy ($p = 0.0012$). Moreover, the risk of proliferative diabetic retinopathy was significantly higher (2.8 times; $p = 0.036$) in the presence of periodontal disease [61].

Of the seven studies identified in our systematic review [27,28], one reported on T1DM [62] and five on T2DM [63–67], whereas one did not specify diabetes type [61].

Longitudinal studies among Pima Indians 35 years and older demonstrate that periodontal disease may predict increased overall mortality [65] as well as the risk of overt nephropathy and end-stage renal disease [66]. Periodontal disease significantly predicted deaths from ischemic heart disease ($p_{trend} = 0.04$) and diabetic nephropathy ($p_{trend} < 0.01$). Those with severe periodontal disease had 3.2 times the risk (95% CI 1.1–9.3) of cardiorenal mortality (ischemic heart disease and diabetic nephropathy combined) compared to those with no, mild, or moderate periodontal disease combined [65]. Similarly, during up to 22 years of follow-up, the incidence of macroalbuminuria was 2.0, 2.1, and 2.6 times higher in individuals who had moderate periodontitis, severe periodontitis, or were edentulous, respectively, compared to those with no or mild periodontitis ($p = 0.01$) [66]. Comparing the same groups, incidence of end-stage renal disease was 2.3, 3.5, and 4.9 times higher ($p = 0.02$). Hence, moderate and severe periodontal disease, as well as edentulousness, significantly predict in a dose-dependent manner both macroalbuminuria and end-stage renal disease among Pima Indians.

Diabetes complications reported to be related to periodontal disease include:

- cardiovascular disease
  - coronary artery disease
  - ischemic heart disease
  - carotid intima media thickening
  - calcification of atherosclerotic plaque
- hypertension
- cerebrovascular events (stroke)
- kidney disease
  - macroalbuminuria
  - proteinuria
  - end-stage renal disease
- death due to cardio-renal disease
- neuropathic foot ulcer
- retinopathy.

Periodontal disease and diabetes-related medical care costs

Medical care costs related to periodontal care

Diabetes care requires immense resources as mentioned earlier. For instance, about USD 8500 is spent annually per diabetes

patient for diabetes care in the US [8]. The most recent estimated US diabetes costs among individuals with diagnosed diabetes in 2012 was 2.3 times higher per patient than for those without diabetes [9]. The total US diabetes costs are USD 245 billion with USD 176 billion spent on direct medical costs and USD 69 billion in indirect costs (disability, work loss, premature death) [9].

Periodontal disease is relatively easy to prevent or manage, as the diseased tissues are easily accessible and treatment occurs at outpatient dental offices or clinics. In addition, inexpensive home-care measures are known to be effective in management or prevention of recurrence. Therefore, it would be of potentially wide-ranging interest to explore whether periodontal care is associated with reduced expenditure for diabetes-related medical services, actually reflecting the potential decreases in healthcare costs. The area of exploring dental and medical insurance claims is a novel avenue to obtain a glimpse of such information. Brief examples of analyses of insurance claims in US studies with different medical care outcomes follow.

Hospitalizations and physician office visits

Among 91,242 insureds with T2DM and both medical and dental insurance, the annual mean number of hospitalizations over a 4-year period was reduced by 39.4%, in the insureds who received periodontal care when compared to insureds who did not receive such care [68].

Provision of monthly oral health procedures by licensed dental hygienists to residents of nursing homes [69] reduces the hospitalization rate by over half, namely 8.8% to 11.7%, compared to the national rate of over 25% [70]. Several studies demonstrate that medical care costs for patients with diabetes are lower for those who obtain preventive or therapeutic periodontal care than for people with diabetes who do not receive periodontal care. For instance, in people with T2DM, costs for medical care were significantly reduced by USD 2840 (from USD 7056 to USD 4216) per subject per year, a 40.2% reduction, for individuals who also received periodontal care compared to those who did not [68]. Another study among insureds with diabetes found that those who received actual periodontal treatment (a proxy for the diagnosis of manifest periodontitis, not only gingivitis) incurred significantly higher per member per month medical costs compared to insureds who only received gingivitis treatment, dental maintenance services, other dental services, or no dental services [71]. However, it was not possible to control for potential confounders such as smoking and socioeconomic factors as the insurance database lacked this information. Furthermore, among 2674 insureds aged 18–64 with diabetes who had simultaneous medical, pharmaceutical, and dental insurance coverage for at least 1 year during a 6-year period, those who received the anti-inflammatory, nonsurgical periodontal procedures: debridement, scaling and root planing ("deep cleaning"), periodontal maintenance therapy, or prophylaxis had significantly lower medical care costs compared to the diabetes group not receiving these dental services for diabetes-related care; diabetes complications care; and total medical care [72].

Periodontal care and glycemic control

Among 5103 dually (medical and dental) insureds 40–70 years old with diabetes, the mean glycated hemoglobin level was 7.66% [73]. The 38% who received some type of periodontal treatment had an average glycated hemoglobin level that was 0.08 percentage points higher than those who did not ($p = 0.02$), likely reflecting the inflammatory effect of periodontal infection. Patients with greater periodontal treatment intensity had significantly lower glycated hemoglobin levels than those receiving treatment of lower intensity. In those with multiple surgeries for treatment of periodontal disease, glycated hemoglobin levels were reduced by 0.36 percentage points ($p = 0.002$) compared to those with no or one periodontal surgery procedure. These findings support the findings from the clinical trials of effects of periodontal treatment on glycemic control (Tables 68.2 and 68.3).

Guidelines for oral health in people with diabetes

Hyperglycemia and periodontal infection adversely affect each other: Poorly controlled diabetes is associated with the incidence, progression, and severity of periodontitis. Similarly, periodontitis decreases glycemic control, increases the risk of diabetes-associated complications, promotes incident diabetes (onset of new diabetes)/impaired fasting glucose, and possibly promotes gestational diabetes. Periodontal treatment—including routine, nonsurgical procedures that can be delivered in general dental practices and clinics—can lead to better glycemic control as well as reduce periodontal inflammation and promote periodontal health.

It is estimated that among the 29.1 million Americans aged 20 years and older who have diabetes, 21.0 million have diagnosed and 8.1 million undiagnosed diabetes [9]. Additionally, 86 million have prediabetes [9]. Consequently, over 115 million—a staggering proportion exceeding one third of the entire adult US population—are affected by diabetes or by a high risk for diabetes. Therefore, even a small improvement in hyperglycemia by attaining and maintaining good oral health could have great beneficial effects on diabetes control, complications, costs, and human suffering. Consequently, prevention or treatment of periodontal infections should become an integral part of the management of diabetes.

International Diabetes Federation (IDF)

For use by people with diabetes and their care providers, the International Diabetes Federation has published guidelines for oral health specifically in people with diabetes [74]. This 11-page booklet named *IDF Guideline on Oral Health for People with Diabetes* is freely available at: http://www.idf.org/webdata/docs/OralHealth_EN_RTP.pdf.

American Diabetes Association (ADA)

Gradually, but slowly, oral health is becoming part of the standards for diabetes care around the world. For instance, up to

and including 2013, the annually updated standards of medical care in diabetes by the American Diabetes Association (ADA) include only referral to a dentist for comprehensive periodontal examination without any further comments or explanations [75]. For the first time, a brief section with two citations on periodontal disease appeared in the 2014 annual January supplement to *Diabetes Care*, on p. S49 in the updated "Standards of Medical Care in Diabetes—2014", which may be freely viewed at: http:// care.diabetesjournals.org/content/37/Supplement_1/S14.full. pdf+html. This paragraph is included in the section "*VII. Assessment of Common Comorbid Conditions.*" It is a positive step by the ADA towards recognizing the importance of oral health in diabetes management.

European Federation of Periodontology (EFP) and the American Academy of Periodontology (AAP)

A consensus report regarding the relationships between periodontal disease and diabetes including suggestions regarding oral care for patients with diabetes and for physicians and dentists who treat patients with diabetes, or patients at risk for diabetes, resulted from the joint European–USA conference of experts [33,34]. These recommendations are displayed in Figure 68.4. The guiding principles can also be publicly viewed at: http://onlinelibrary.wiley.com/doi/10.1111/jcpe.12077/pdf.

Co-management of patients with diabetes by dental and medical care providers

Patient-centered collaboration between healthcare professionals to prevent, control, and manage both periodontitis and diabetes is a reasonable goal since good glycemic control and good oral hygiene in people with diabetes will decrease the risk for development of periodontal disease and tooth loss. Conversely, attaining and sustaining periodontal health will prevent increased blood glucose levels due to periodontal infection. Despite the importance of assessing the oral cavity for (especially periodontal) infection as an integral part of the comprehensive medical care of diabetes patients, such attention seems to still be generally lacking in the medical community. However, the dental profession is increasingly concerned with the importance of good periodontal health in patients with diabetes as well as considering the possible presence of undiagnosed diabetes in these patients.

Focus on oral health in medical practice: why medical health professionals should pay attention to the health of the mouth

The health of and care for the oral cavity has become increasingly separated from the rest of the body. Although the concept of the strong oral-systemic connection is not new, it was often lost in our modern specialization. However, recent attention has focused on the mutually important effects between the mouth and the body and novel techniques are now available to explain some of the mechanisms underlying such relationships. Both periodontal disease and diabetes are chronic diseases that increase with age, and it is now known that they mutually influence each other and share common risk factors such as poor diet, obesity, and smoking. Consequently, it becomes imperative to make every effort to ensure that good oral health is attained and maintained. This is increasingly important as more people keep their teeth into old age and there is a tendency to be less willing to part with their teeth.

Many studies show that people with diabetes feel that their oral health negatively affects their quality of life [76–78]. A Brazilian study among persons with diabetes even demonstrated that oral health affected those who had mild to moderately severe periodontal disease more negatively than those with healthy periodontal tissues or only gingivitis [79].

There is very limited interprofessional education among the healthcare professions in most countries regarding the oral cavity and the ways in which systemic diseases and conditions manifest themselves in the oral tissues—often prior to exhibiting signs elsewhere in the body.

Several reports from the Institute of Medicine (IOM) and other professional associations and foundations emphasize the need for better integration of healthcare in the future and the various communities of health professionals are beginning to realize the potential benefits of such an integration [80]. For instance, the concept of a medical home with patient-centered interprofessional collaboration to manage patients is slowly gaining ground [81,82].

Focus on diabetes in the dental office: should dental health professionals screen for diabetes?

About 70% of the US population visit a dentist within a year [83], and it is likely that this is the case in many other developed countries. Therefore, it is reasonable to propose the dental visit may offer a largely untapped opportunity to screen for undiagnosed diabetes and prediabetes, which could lead to referral of patients for further medical evaluation and care. Especially beneficial would be the early detection of elevated risk of hyperglycemia, prediabetes, since early lifestyle intervention may prevent or delay the onset of diabetes. It is estimated that among the approximately 25% of people in the US who do not receive any general outpatient healthcare visits, over one quarter did visit a dental office or clinic. Therefore, dental practices can serve as alternate sites of opportunity to identify general health concerns [84].

The American Diabetes Association recommends that testing to detect T2DM and assess risk for future diabetes in

Figure 68.4 Suggestions by the EFP/AAP Working Group Regarding Oral Health Care for Persons Who Have Diabetes (or Risk Therefore) and Their Dental and Medical Care Providers for: (A) physicians and other medical health professions for use in diabetes practice; (B) dentist's use in dental practice; (C) physician's practice/office; and (D) patients at the dental surgery/office who have diabetes or are found to be at risk for diabetes. A Suggested Guidelines for Physicians and Other Medical Health Professions for Use in Diabetes Practice

Oral health of my patients

Because of the increased risk for developing periodontitis in patients with diabetes, the following recommendations are made:

- Patients with diabetes should be told that periodontal disease risk is increased by diabetes. They should also be told that if they suffer from periodontal disease, their glycaemic control may be more difficult, and they are at higher risk for diabetic complications such as cardiovascular and kidney disease.
- As part of their initial evaluation, patients with type 1, type 2 and gestational diabetes (GDM) should receive a thorough oral examination, which includes a comprehensive periodontal examination.
- For all newly diagnosed type 1 and type 2 diabetes patients, subsequent periodontal examinations should occur (as directed by the dental professionals) as part of their ongoing management of diabetes. Even if no periodontitis is diagnosed initially, annual periodontal review is recommended.
- Diabetes patients presenting with any overt signs and symptoms of periodontitis, including:
  ○ loose teeth not associated with trauma
  ○ spacing or spreading of the teeth
  ○ gingival abscesses
  ○ gingival suppuration
    require prompt periodontal evaluation.
- Patients with diabetes who have extensive tooth loss should be encouraged to pursue dental rehabilitation to restore adequate mastication for proper nutrition.
  ○ Oral health education should be provided to all patients with diabetes.
- For children and adolescents diagnosed with diabetes, annual oral screening is recommended from the age of 6–7 years by referral to a dental professional.
  ○ Patients with diabetes should be advised that other oral conditions such as dry mouth and burning mouth may occur, and if so, they should seek advice from their dental practitioner. Also patients with diabetes are at increased risk of oral fungal infections and experience poorer wound healing than those who do not have diabetes.

B Suggested guidelines for use in dental practice

My patient with diabetes

- Patients with diabetes should be told that they are at increased risk for periodontitis. They should also be told that if they suffer from periodontal disease, their glycaemic control may be more difficult, and they are at higher risk for other complications such as cardiovascular and kidney disease.
- Patients presenting with a diagnosis of type 1, type 2 or gestational diabetes should receive a thorough oral examination, which includes a comprehensive periodontal evaluation.
- If periodontitis is diagnosed, it should be properly managed. If no periodontitis is diagnosed initially, patients with diabetes should be placed on a preventive care regime and monitored regularly for periodontal changes.
- Patients with diabetes presenting with any acute oral/periodontal infections require prompt oral/periodontal care.
- Patients with diabetes who have extensive tooth loss should be encouraged to pursue dental rehabilitation to restore adequate mastication for proper nutrition.
- Oral health education should be provided to all patients with diabetes.
- Patients with diabetes should also be evaluated for other potential oral complications, including dry mouth, burning mouth and candida infections.
- For children and adolescents diagnosed with diabetes, an annual oral screening for early signs of periodontal involvement is recommended starting at the age of 6 years.
- Patients who present without a diabetes diagnosis, but with obvious risk factors for type 2 diabetes and signs of periodontitis should be informed about their risk for having diabetes, assessed using a chair-side HbA1C test, and/or referred to a physician for appropriate diagnostic testing and follow-up care.

C Recommendations for patients with diabetes at the physician's practice/office

Why should I have my gums checked?

If your physician has told you that you have diabetes, you should make an appointment with a dentist to have your mouth and gums checked. This is because people with diabetes have a higher chance of getting gum disease. Gum disease can lead to tooth loss and may make your diabetes harder to control.

You may have gum disease if you have ever noticed:

- Red, bleeding or swollen gums;
- Pus from the gums;
- Foul taste;
- Longer looking teeth;
- Loose teeth;
- Increasing spaces between your teeth;
- Calculus (tartar) on your teeth.

If you have noticed any of these problems, it is important to see a dentist as soon as possible. Gum disease may be present and get worse with no apparent symptoms to you, so even if

you do not think you have gum disease now, you should still get regular dental check-ups as part of managing your diabetes. Your dentist will be able to pick up early signs of gum disease.

You also need to clean your teeth and gums very carefully at home.

If you have diabetes, you may also suffer from dry mouth, burning mouth, yeast infections of the mouth or poor healing of mouth wounds.

It is important to keep your mouth and your whole body as healthy as possible with regular dental and medical care.

D Recommendations for patients at the dental surgery/office who have diabetes or are found to be at risk for diabetes

You have diabetes or you have been told by your dentist you are at risk for diabetes

People with diabetes have a higher chance of getting gum disease.

If you have been told by your dentist that you have gum disease, you should follow up with necessary treatment as advised. This may require several appointments. Like diabetes, gum disease is a chronic condition and requires lifelong maintenance.

You also need to clean your teeth and gums very carefully at home.

If left untreated, gum disease may also make your diabetes harder to control. Gum disease may be present and get worse with no apparent symptoms to you, so if your dentist told you that you do not have gum disease now, you should still get regular dental check-ups as part of managing your diabetes. Your dentist will be able to pick up early signs of gum disease.

You may have gum disease if you ever notice:

- Red, bleeding or swollen gums;
- Pus from the gums;
- Foul taste;
- Longer looking teeth;
- Loose teeth;
- Increasing spaces between your teeth;
- Calculus (tartar) on your teeth.

People with diabetes may also suffer from dry mouth, burning mouth, yeast infections of the mouth or poor healing of mouth wounds.

If you do not have diabetes, but your dentist identified some risk factors for diabetes including signs of gum disease, it is important to get a medical check-up as advised.

Your medical doctor can order blood tests to see if you have diabetes and not know it, and can provide proper advice and care based on the results. Make an appointment to see your medical doctor as soon as possible. And remember to inform your dentist about the outcome of your visit to the medical doctor.

It is important to keep your mouth and your whole body as healthy as possible with regular dental and medical care.

asymptomatic people should be considered in adults of any age who are overweight or obese (BMI $\geq 25\,kg\,m^{-2}$) or have one or more additional risk factors for diabetes. In those without these risk factors, testing should begin at age 45 years [75].

Several studies suggest a patient with periodontal disease is at risk for diabetes [85–89]. Therefore, presence of periodontal disease can be used as an additional criterion for screening for diabetes in the dental office [23]. Lalla and colleagues demonstrated that having at least 26% of teeth with deep pockets or missing at least four teeth correctly identified about three-quarters (72–75%) of prediabetes or diabetes cases [87].

Several surveys indicate that dental professionals are interested in and willing to engage in evaluation, screening, and monitoring systemic conditions and diseases, as well as to collaborate more closely with other healthcare professionals. For example, findings from a study assessing dentists' attitudes, willingness, and perceived barriers regarding chair-side medical screening in the dental office show that of the 1945 responding dentists, about three-quarters (76.6%) regarded it important to conduct screening for diabetes, with similar results for other systemic conditions such as hypertension (85.8%), cardiovascular disease (76.8%), hepatitis (71.5%), and human immunodeficiency virus infection (68.8%) [90]. The vast majority were willing to refer patients for consultation with physicians (96.4%), collect oral fluids for salivary diagnostics (87.7%), and conduct medical screenings that yield immediate results (83.4%). About half would collect blood via finger stick (55.9%). Respondents were significantly more willing to collect saliva than height and weight measurements or blood via finger stick. Insurance reimbursement turned out to be significantly less important than time, cost, liability, or patients' willingness. Confirmation of the latter was demonstrated among elder minorities during community-based oral health screening sessions that integrated screening for diabetes and hypertension into its oral health activities at senior centers [81].

A recent study screening dental patients for diabetes reported that about 40% of patients attending a dental office visit were found to have elevated HbA1c ($\geq$5.7%) when referred for medical diagnosis. Only 21% from dental offices compared to 85% from Comprehensive Care Clinics sought the medical diagnosis from a physician after referral. This study identified possible barriers, that is, dental patients' hesitancy to follow up with medical referrals may be due to costs, denial, or some other factors. These barriers did not seem to exist in the Community Care Clinic. Factors that facilitate and encourage follow-up with diabetes referral in similar studies may help us understand these barriers and develop strategies to overcome them [91].

For dental professionals to engage in identification and management of prediabetes and diabetes and to collaborate closely with other health professionals requires a paradigm shift, as well as proper education [92]. Attitudes of dental care providers, medical professionals, and patients and the individuals engaged in their health will need to shift towards regarding all professionals who engage in attaining and maintaining the patient's good health as members of an interprofessional team. One approach is to engage dental health professionals in managing risk factors common to periodontal disease and diabetes. These common risk factors include smoking and diet, especially refined sugar consumption [93]. We all need to see ourselves as partners who assume important roles in the patient-centered healthcare team whose collaboration is necessary for obtaining the goal of the best health possible for each patient.

Future healthcare collaboration for diabetes prevention and lifelong management

In recent history, health professions' education and healthcare practices have developed and functioned separately, with little recognition of the fact that they are all inextricably linked. However, rapid redesign of healthcare delivery, stimulated in the US in part by the Affordable Care Act, is occurring alongside, but independently of, educational reform of the health professions. For instance, health professionals participating in a conference in January 2013 envisioned a healthcare system in which learners and practitioners across the professions are working collaboratively with patients, families, and communities, and with each other [94]. The Healthy People Curriculum Task Force is a consortium of eight health professions education associations. It has developed The Education for Health Framework and connected the framework with new and revised educational objectives of Healthy People 2020. Interprofessional prevention education, in which health professionals learn and practice together, is seen by the Task Force as a key method for implementation [95].

Team care is likely to become an important component of future healthcare systems designed to provide comprehensive lifetime prevention and management of chronic diseases such as diabetes, in which dental professionals may play an important role. The "team care" guide named *Redesigning the Health Care Team: Diabetes Prevention and Lifelong Management* is a 48-page document created by the US National Diabetes Education Program [96]. These programs are designed for the US healthcare system and may not be ideal for other countries, but in general, integrated interprofessional healthcare is important and likely to benefit patients suffering from diabetes and periodontitis throughout the world. The guide may be accessed at: http:// ndep.nih.gov/media/NDEP37_RedesignTeamCare_4c_508.pdf.

Physicians' provision of more comprehensive and effective oral health advisory and routine communication with dentists is part of the expanded physician role consistent with the evolving patient-centered medical–dental home or "chronic care model" of the future [97,98]. Similarly, dental professionals should be vigilant regarding their patients' general health and refer as necessary for medical evaluation.

The time has come for all healthcare professionals to collaborate and co-manage their mutual patients with diabetes — or at risk for developing diabetes — for potential human and financial benefits for the patients and societies globally.

Complications of diabetes: macrovascular

Epidemiology of macrovascular disease and hypertension in diabetes mellitus

Introduction

Diabetic patients suffer from cardiovascular disease (CVD) and the majority of both type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM) patients die from CVD. Epidemiologic studies of CVD in diabetes are important for the estimation of the magnitude and the nature of the problem, for the identification of the risk factors for CVD in diabetic subjects, and for the development of preventive measures. It has been proposed that diabetes and macrovascular disease may both have common genetic or environmental antecedents. This "common soil" hypothesis for diabetes and macrovascular diseases has received more support from the numerous epidemiologic studies during the last few years [1]. The major forms of CVD, that is, coronary heart disease (CHD), stroke and peripheral vascular disease (PVD), share both an atherosclerotic background and several common risk factors.

Hypertension

Prevalence and incidence

It has been known for decades that the prevalence of hypertension in diabetic individuals appears to be approximately twice as high as in nondiabetic people in the same population [2–4]. It is more frequent in men than in women before the fifth decade and more frequent in women thereafter [5]. The prevalence of coexisting diabetes and hypertension is higher in US Blacks compared with Whites; both conditions are more common among the lower socioeconomic groups [6–8].

The prevalence of hypertension among young T1DM patients is dramatically increased. Data from the Joslin clinic showed that 15.5% of males with diabetes aged 18–24 years had hypertension compared with only 1.7% in the general population—excess risk of 13.8% [9]. A much lower prevalence of hypertension was found in females in the same age group: 2.4% versus 0.8%, respectively. Others have also reported a significant increase in blood pressure (BP) in T1DM males but not in T1DM females [10]. In the general population BP levels are higher in men than in women until the age of 45–50 years, and this may also be reflected in young diabetic subjects. Nevertheless, other studies suggest that significant increases in BP in T1DM patients are seen in both sexes [11].

Epidemiologic evidence is unequivocal and uniform, showing that patients with T2DM have a higher prevalence of hypertension than do nondiabetic subjects at any age, in both sexes and regardless of BP levels in the background population [12]. The problem for the interpretation of the available epidemiologic data is that in many studies control for degree of obesity was not done or remained unclear. The increased prevalence of hypertension in the diabetic population (especially T2DM) may to some extent be due to improved screening since diabetic patients use more health services, and due to the lower thresholds for treatment of high BP in diabetic patients [13].

The definition for hypertension has changed over the years, and also varies to some extent between countries. The most recent criteria of the US Eight Joint National Committee (JNC8) were issued in 2014 1999 [14]. In general, the JNC8 and World Health Organization/International Society of Hypertension (WHO/ISH) define hypertension as an office BP exceeding 140

and/or 90 mmHg (Korotkoff I–V). The JNC8 statees that there is strong evidence to support treating hypertensive persons aged 60 years or older to a BP goal of less than 150/90 mmHg and hypertensive persons 30 through 59 years of age to a diastolic goal of less than 90 mmHg; however, there is insufficient evidence in hypertensive persons younger than 60 years for a systolic goal, or in those younger than 30 years for a diastolic goal, so the panel recommends a BP of less than 140/90 mmHg for those groups based on expert opinion. The same thresholds and goals are recommended for hypertensive adults with diabetes or nondiabetic chronic kidney disease (CKD) as for the general hypertensive population younger than 60 years [14].

There are a few studies that have shown that in T2DM the increase in BP is, at last in part, independent of body weight [12,15,16]. While T1DM patients are usually normotensive until overt renal disease develops, the prevalence of hypertension increases markedly in T2DM before the proteinuric state [17,18]. About one fourth of T2DM patients are already hypertensive at the time of diagnosis of diabetes [3,17,19].

Proteinuria/Microalbuminuria and BP

Microalbuminuria is in most cases the first sign of the diabetic renal disease in both T1DM and T2DM patients. The prevalence of microalbuminuria among diabetic patients is 15–20% [20–22] and it is higher in T1DM than T2DM patients. On the other hand, more or less severe signs of diabetic renal disease may be found in as many as 41% of both T1DM and T2DM patients once the duration of diabetes is long enough [22]. It is possible that high BP in diabetic patients with either microalbuminuria or nephropathy is genetically determined, but the susceptibility genes have not been identified yet. There is little question that BP is higher, even within the normal range, in T1DM patients with microalbuminuria compared with normoalbuminuric patients [23]. However, whether BP rises before or after the development of microalbuminuria has been debated. Mathiesen et al. [24] found no difference in BP between those who did and those who did not develop persistent microalbuminuria until microalbuminuria had been present at least 3 years, indicating that BP elevation is secondary to the initiation of diabetic nephropathy. Raal et al. [25] found no difference in BP at baseline between individuals who remained normoalbuminuric and those who later progressed to diabetic renal disease. Nevertheless, the development of microalbuminuria was accompanied by a parallel rise in diastolic BP, indicating that BP elevation and the initial stage of diabetic renal disease are concurrent events. Kimball et al. [23] also suggested that the alterations in cardiovascular and renal function may occur in parallel in adolescents with T1DM. However, some studies suggested that BP may rise before the detection of microalbuminuria and may even serve as a predictor of its development [26–28]. Results from the EURODIAB T1DM Complications Study [29] also suggest that raised albumin

excretion is a response to, and not necessarily a cause of, mildly raised BP.

The pathogenetic relationship between elevated BP and renal disease in T2DM is more difficult to establish than in T1DM. Often the time of onset of T2DM cannot be precisely defined, and some 40–50% of T2DM patients receive antihypertensive treatment at the time of diagnosis [30]. It has been shown that elevated BP is an independent predictor of T2DM and glucose intolerance [4]. However, BP starts to increase steeply when persistent proteinuria develops in T2DM patients [31], and evidence exists that BP may start to rise before the development of microalbuminuria not only in T2DM patients but also in T1DM patients [27,31]. It is possible that in many hypertensive patients with T2DM, diabetes itself is not causally related to elevated BP, since even in nondiabetic populations of the same age hypertension is very common.

Hyperinsulinemia/insulin resistance and BP

Numerous conditions associated with insulin resistance and/or hyperinsulinemia are frequently accompanied by hypertension. This conclusion applies not only to obesity [32,33], impaired glucose tolerance (IGT) [34], or T2DM [35], but also to T1DM [36] when insulin sensitivity is impaired [37]. It has been suggested that hyperinsulinemia, which occurs with insulin resistance, increases BP primarily through an increase of sodium retention, stimulation of sympathetic nervous activity, or both [38]. However, epidemiologic and clinical data linking hyperinsulinemia to hypertension are inconsistent. There is support for the insulin–BP association in some Caucasoid populations [34,39], case-control studies [40–42], or cross-sectional studies [43,44], but a number of studies in ethnic groups including Europids [45–47], Micronesians, Polynesians, and Melanesians [48], Pima Indians [49,50], African Americans [49], Asian Indian, Creole, and Chinese Mauritians [51] do not support the hypothesis. Interestingly, these latter populations have substantially higher circulating insulin concentrations than do, for instance, Europid populations, and yet, their BP levels are not higher or may be even somewhat lower. In addition, insulin resistance has not always been demonstrated in patients with essential hypertension. Patients with severe hyperinsulinemia due to an islet cell tumor, for example, display neither hypertension nor hyperglycemia [52]. Likewise, the supraphysiologic dose of insulin administered to patients with T1DM is not always associated with hypertension [53]. One study indicated a correlation between insulin and BP only in subjects with a positive family history of hypertension or diabetes and suggested a possible genetic influence on insulin resistance [54]. A role of a familial component in insulin resistance syndrome is also suggested by studies showing that young adult normotensive offspring of hypertensive parents are more insulin resistant than offspring of normotensive parents [55]. Doria et al. [56] suggested that insulin resistance occurs

only in those hypertensive subjects with high erythrocyte sodium–lithium countertransport.

Inconsistency in association between insulin and hypertension can be in part explained by the hemodynamic effects of insulin. There is a strong evidence that acute physiologic increments in plasma insulin concentrations (euglycemic clamp) stimulate the sympathetic noradrenergic activity, which is offset by its vasodilator action on skeletal muscle blood flow [57]. The acute vasodilatory effect of insulin may be through alteration of intracellular calcium handling. Saito et al. [58] found that insulin attenuated angiotensin II stimulated increases in cytosolic free calcium by decreasing the pool of inositol triphosphate (IP_3) releasable calcium, an effect blocked by inhibition of nitric oxide generation. More recent studies show an important effect of insulin on the vascular production of endothelin 1 [59].

The opposing hemodynamic effects of insulin help explain why acute physiologic hyperinsulinemia does not elevate BP in normal human beings [60]. Baron et al. [61] hypothesize that insulin resistance and hyperinsulinemia are markers of the hypertensive process in the muscle and not contributors to elevated BP. A sympathetic overactivity could also lead to insulin resistance and a compensatory increase in plasma insulin levels [62,63]. The recent line of research related to insulin has been targeted to endothelial dysfunction [64]. Hyperinsulinemia (or insulin resistance) seems to abrogate endothelium-dependent vasodilation in large arteries. One of the proposed mechanisms includes oxidative stress caused by hyperinsulinemia.

Attenuation in the balance between insulin's depressor and pressor effects could influence BP regulation. Insulin-mediated stimulation of skeletal muscle blood flow is reduced in obese subjects [65] and T2DM patients [66]. However, several clinical studies have failed to show any effect of acute physiologic hyperinsulinemia on BP in obese, insulin-resistant hypertensive patients [67–69]. Thus it is probable that hyperinsulinemia is not directly causing hypertension, but may serve as an indicator of a common antecedent (either genetic or environmental) of T2DM and hypertension. In studies of Mexican Americans a number of factors including typical CVD risk factors such as high total cholesterol, BP, fasting glucose, body mass index (BMI), triglycerides, and low high-density lipoprotein (HDL) cholesterol predicted the development of T2DM, but their effect was virtually removed after adjusting for fasting insulin [70]. This study strongly suggested that prediabetic individuals who are insulin resistant are at a higher risk of developing CVD than are insulin-sensitive prediabetic individuals, pointing out the importance of hyperinsulinemia in targeting prevention [71].

Hyperglycemia and BP

Hyperglycemia is the distinguishing feature of diabetes. The joint data from Finnish and Dutch cohorts of the Seven Countries Study with 30 years of follow-up showed that in men with T2DM or IGT, BP levels and the prevalence of hypertension were higher than in normoglycemic men. Interestingly, these differences in BP had already been seen 20–30 years earlier. An elevation in BP preceded abnormal glucose tolerance but not hyperinsulinemia. BMI levels of men with hyperinsulinemia had been shown to be higher 20–30 years earlier, but BP levels had not. Thus, it was proposed that glucose intolerance is a stronger correlate of hypertension than is hyperinsulinemia [72].

The hypothesis of oxidative stress through which high glucose levels may play a role in cardiovascular complications has been increasingly discussed [73,74]. The endothelium has been shown to release a substance that induces smooth muscle relaxation by increasing the production of cyclic guanosine monophosphate. This factor is called endothelium-derived relaxing factor, and nitric oxide is believed to be one of such factors [75]. Vessels of healthy people are continuously dilated by nitric oxide released from endothelial cells. Exposure to elevated concentrations of glucose *in vitro* causes selective impairment of endothelium-dependent relaxation [76]. Oxidative stress induced by hyperglycemia is implicated as a source of altered endothelially mediated relaxation in diabetes. It was shown in experimental studies that oxygen-derived free radicals inactivate endothelium-derived releasing factors [77] and selectively attenuate endothelium-dependent relaxation [78]. One possible source of oxygen-derived free radicals in diabetes is autoxidation of glucose [79]. Glucose can autoxidize, generating free radicals, hydrogen peroxide, and reactive ketoaldehydes. These last compounds may largely participate in the formation of glycated proteins, which are themselves a source of oxygen-derived free radicals [80,81]. The possibility that oxygen-derived free radicals play a role in the pathogenesis of vascular complications of diabetes is suggested by studies that have shown that antioxidants such as vitamin E, superoxide dismutase, catalase, glutathione, and ascorbic acid are all decreased in tissues and blood of diabetic patients [82,83]. Also elevated levels of products of oxygen-derived free radicals have been reported in diabetic patients [84,85]. In a study by Ceriello et al. [86], the plasma concentration of O^- was elevated in patients with T1DM, but showed a trend to normalization after strict metabolic control. There was a strong correlation between plasma glucose concentrations and O^- concentrations in both normal subjects and diabetic patients over a wide range of glucose concentrations. An acute antihypertensive effect of antioxidant agents, such as vitamin C, thiopronine, and glutathione, has been reported in hypertensive subjects, regardless of whether they are diabetic patients [86]. During the postprandial state, not only hyperglycemia occurs, but also hyperlipidemia. More recently, it was confirmed that both postprandial hypertriglyceridemia and hyperglycemia have independent and cumulative deleterious effect on endothelial function and suggested that oxidative stress is the common mediator through which they exert such effect [87].

Diurnal blood pressure variability

BP and heart rate are principally under the control of the autonomic nervous system. It has been proposed that loss of the normal day–night difference in BP may be a sign of early autonomic dysfunction in diabetic patients. In normotensive T1DM and T2DM patients during sleep there is loss of the nocturnal dip of BP seen in normal subjects, and diabetic patients also have increased BP variability [88–90]. These may be contributing factors to the development of hypertension and the accelerated cardiovascular damage seen in diabetes [88]. In addition, left ventricular mass is increased [91–94], asymptomatic cerebrovascular damage is more advanced [95], and history of stroke is more frequent [96] in nondiabetic hypertensive nondippers as compared with dippers. Thus, for any given level of daytime BP, a persistent pressure overload could speed the progression of hypertensive organ damage and thereby result in a higher incidence of cardiovascular events. Since cardiovascular risk in hypertension is somewhat lower in nondiabetic women than in men, the detrimental effect of persistently high BP levels over 24 h would become particularly evident in diabetic women, thus raising their risk to the level occurring in men [97]. A study on determinants of ambulatory 24-h BP in T1DM patients has shown that the mean male–female difference in 24-h diastolic BP was 5.6 mmHg less in diabetic patients than in healthy individuals after adjusting for all other variables [98]. These findings are in concert with the reported loss in diabetic women of the relative female protection against cardiovascular and cerebrovascular diseases [99,100].

Atherosclerosis

Diabetic subjects show more widespread and more severe coronary atherosclerosis. Data supporting this opinion emerge equally from postmortem [101–103] and from clinical and epidemiologic studies [104]. The Five Town Study [105] found more extensive atherosclerosis in the coronary arteries and abdominal aortae of diabetic subjects than in the groups that represented "standardized average" atherosclerosis in the background population. In addition, there was a tendency for an increased severity of atherosclerosis when both diabetes and hypertension had been present in life. Another WHO study on the prevalence of large vessel disease among diabetic populations in 14 European centers suggested the following [106]:

1 The prevalence of large vessel disease varies considerably between different centers, the highest being in Eastern Europe. This corresponds to the prevalence of CVD in the general population.
2 The prevalence of all large vessel disease is at least the same in diabetic women as in diabetic men. The overrepresentation of women seems particularly great in centers where the overall prevalence of atherosclerotic diseases is high.
3 The female overrepresentation is due to CHD while the prevalence of PVD is higher in men than in women in most centers.
  The first statement is in agreement with the observations from the International Atherosclerosis Project [107].

At least two studies were designed to evaluate the severity of coronary artery disease specifically in juvenile-onset T1DM. One was an autopsy study, in which coronary pathology of nine young patients with T1DM was compared with a group of nine age-matched individuals without diabetes [107,108]. None of the individuals in either group had a clinical history of angina pectoris. Six of the nine diabetic patients had a >75% reduction in luminal diameter, while none of the nondiabetic subjects had this degree of narrowing. Another study examined clinical and angiographic findings in 32 patients with T1DM and 31 nondiabetic patients, matched for age and symptoms [109]. In comparison with nondiabetic individuals, patients with T1DM were significantly more likely to have severe (>70%) narrowings, to have them in all three major coronary arteries (47% vs. 6%), and to have them in distal segments. Severe narrowings of multiple vessels were significantly more common in men than in women and in individuals who also had hypercholesterolemia.

In the only population-based autopsy study, autopsies were evaluated in 83 diabetic and 159 nondiabetic Japanese American men from the Honolulu Heart Program [103]. Diabetic men had an excess of coronary atherosclerosis and of acute, healing, or fibrotic myocardial lesions; the latter but not the former association was independent of major CHD risk factors. This suggests that the atherosclerotic process is mediated by BP, cholesterol, and smoking, while in men with diabetes one or more modes of action besides atherosclerosis also seem to account for the excess of heart disease.

Results from other autopsy studies have shown that diabetic patients have a higher incidence of two- and three-vessel disease, and a lower incidence of single-vessel disease, compared with patients without diabetes. In a report by Natali et al., the incidence of multivessel disease was as high as 36% in individuals with diabetes compared with 17% in nondiabetic individuals ($p < 0.0001$) [110]. Retrospective analyses of patients undergoing elective percutaneous transluminal coronary angioplasty (PTCA) support these data. Stein and coworkers analyzed results from 1133 diabetic and 9300 nondiabetic patients undergoing PTCA and showed that the patients with diabetes had a higher rate of multivessel disease than did those without diabetes [111]. The Thrombolysis and Angioplasty in Myocardial Infarction Trial involved 148 diabetic patients and 923 nondiabetic patients [112]. Patients with diabetes had a significantly higher incidence of multivessel disease (66%) than did the patients without diabetes (46%, $p = 0.0001$). In addition, the number of diseased vessels per patient was greater among patients with diabetes compared with those without diabetes.

The effect of diabetes on cerebral and peripheral circulation has been studied extensively during the last decades. Chan et al. [113], using noninvasive methods, compared the prevalence of carotid artery stenoses (50% reduction or more) in 286 volunteer T2DM subjects and 135 controls of similar age (mean 61 and 60 years, respectively); 7% of the diabetic subjects and 1% of controls had severe stenoses. Pujia et al. [114] examined carotid arteries of 54 T2DM subjects and 54 sex- and

age-matched control subjects using echo-Doppler examination. The prevalence of carotid atherosclerosis was 46% in T2DM subjects and 18% in control subjects. Yamasaki et al. [115] assessed the carotid arteries in 105 patients with T1DM (age 4–25 years, duration of diabetes 0.5–17 years), 529 patients with T2DM (age 31–86 years, duration of diabetes 0.5–49 years), and 104 nondiabetic healthy subjects. The intimal plus medial thickness (IMT) values of the arterial wall for T1DM patients aged 10–25 years were significantly greater than those in age-matched nondiabetic subjects. T2DM patients showed IMT values equivalent to those in normal adults over 20 years old. A cross-sectional study on the relation of carotid artery stiffness indices with glucose intolerance and serum insulin concentrations found that persons with T2DM or borderline glucose intolerance had stiffer arteries than did their counterparts with normal glucose tolerance [116]. According to the results of the Insulin Resistance Atherosclerosis Study, diabetes was significantly associated with increased atherosclerosis in the internal carotid artery as determined by IMT [117]. Several studies reported a higher degree of early atherosclerosis in newly detected type 2 diabetic patients than in nondiabetic subjects [118,119]. This suggests that hyperglycemia together with clustering of risk factors, particularly dyslipidemia, may cause intimal–medial thickening already in the early phases of diabetes.

Kingsbury [120] studied 338 male nondiabetic subjects referred to a surgical clinic specializing in PVD. Arteriography was performed in each subject and the degree of irregularity classified into three grades of severity. Both fasting and 2-h blood glucose levels were related to the degree of irregularity, independent of age. The mean ages of men in the "moderate" and "extensive" categories of PVD were 59 and 61 years, respectively. Thus, nondiabetic men at increased risk of T2DM (because of relative glucose intolerance) seem to have more extensive PVD. In the Schwabing Study [121], more than 600 T1DM and T2DM patients were prospectively followed for low-extremity arterial disease, for example PVD by ultrasonic Doppler measurements. Both at the 5-year and 9-year follow-up, the incidence of mostly asymptomatic was consistently and significantly associated with baseline BP and the dyslipidemic complex of high-serum triglycerides/low-HDL cholesterol, but not with total cholesterol or weight. The association with HbA1, plasma C-peptide, and daily insulin dose (in insulin-treated T2DM) was weaker and at 9-year follow-up only significant in univariate analysis. Of diabetic patients dying from cardiovascular causes within 5-year observation, 67% had PVD (mostly asymptomatic) at baseline compared with 15% in those who survived.

Mozes et al. [122] compared the histomorphologic appearance of atherosclerosis in amputated legs of diabetic (10 type 2, 4 unclassified) and nondiabetic patients (n =14). In diabetic patients occlusive disease in amputated legs was more severe in arteries above the ankle than in nondiabetic patients while no difference was found in this series in arteries of the ankle and foot. Also medial calcification in the arteries tended to

be more prominent in diabetic patients than in nondiabetic patients [122]. Jude and collaborators [123] performed the first study that compared angiographic findings between diabetic and nondiabetic patients with PVD. This study showed that in a group of patients referred for angiography of the lower extremity, diabetic patients have worse angiographic findings, more amputations (41.4% vs. 11.5%), and higher mortality than do nondiabetic patients [123].

Many other studies confirm an association between diabetes and increased prevalence of PVD. Individuals with diabetes have 2–4-fold increase in the rates of PVD [124], more often have femoral bruits and absent pedal pulses [125], and have rates of abnormal ankle–brachial indices ranging from 11.9% to 16% [126,127]. The duration and severity of diabetes correlate with incidence and extent of PVD [123]. Patients with diabetes have a greater risk of intermittent claudication, gangrene (10-fold), and amputations (15–20-fold) [128,129]. In the Framingham cohort, the presence of diabetes increased the risk of claudication by 3.5-fold in men and 8.6-fold in women [130]. Overall, diabetes causes most nontraumatic lower extremity amputations in the United States [131]. The relative risk estimate for lower extremity amputation in patients with diabetes was 12.7 compared with that of nondiabetic patients in the Medicare population and as high as 23.5 for diabetic persons aged 65–74 years. Inconsistency exists regarding the question of whether PVD is more commonly symptomatic or asymptomatic among patients with diabetes [129,132].

Coronary heart disease

Prevalence and incidence

There are geographical differences in the prevalence of CHD among cohorts of diabetic patients, and in the incidence of CHD in the general population [133]. Although CHD is a relatively rare cause of death in the first 30 years of T1DM, it is much more common in later years, accounting for up to 30% of deaths in those with T1DM for more than 40 years. A study of 370 male employees with T1DM of a US company showed that death rates in diabetic subjects were more than double than in healthy controls during a 10-year period [134]. Mortality ratios were highest under the age 45, mainly because of increased risk of CHD. Researchers at the Joslin clinic reported that after 20–40 years duration of diabetes 33% of patients aged 45–59 years had either symptomatic or asymptomatic CHD [135]. This is likely to be an underestimate however, as only survivors were included in the study population. Four occupational/population-based studies from the United States found an increased risk of incident heart disease (fatal and nonfatal combined) among diabetic persons [104,136–138]. National survey data from the United States on adults with T2DM have shown a prevalence of fatal and nonfatal CHD events of around 4% for those aged 18–44 years and 20% for those older than 65 years [139]. These rates are 2–20 times higher than corresponding ones for

similar-aged people without T2DM, the rate-ratios being highest among younger patients with T2DM. Uusitupa et al. [140] have also found that age-standardized prevalence of acute myocardial infarction (AMI) among newly diagnosed T2DM men (17%) and women (18%) was significantly higher than among nondiabetic ones (10% and 4%, respectively). Also the incidence of first myocardial infarction (MI) was significantly higher among diabetic compared with nondiabetic persons (for men 27% vs. 19%; for women 12% vs. 2%) during the 10-year follow-up. Age-standardized cardiovascular mortality was substantially higher in diabetic men (15%) and women (17%) than in nondiabetic men (5%) and women (2%).

In one population-based study, the 7-year incidence of first MI or death for patients with diabetes was 20% but was only 3.5% for nondiabetic patients [141]. History of MI increased the rate of recurrent MI or cardiovascular death for both groups (18.8% in nondiabetic persons and 45% in those with diabetes). Thus, patients with diabetes but without previous MI carry the same level of risk for subsequent acute coronary events as nondiabetic patients with previous MI. This study and other findings were considered when the US National Cholesterol Education Program Adult Treatment Panel III proposed that more intense interventions should be considered for diabetic than nondiabetic subjects to prevent CHD [142].

Many studies have shown a considerable 2–8-fold excess in CVD mortality in insulin-treated diabetic subjects compared with the general population [143–147]. Cardiovascular mortality has been estimated to be 2.5-fold higher in T2DM men and 2.9-fold higher in T2DM women compared with nondiabetic subjects. Those treated with oral hypoglycemic agents had higher rates of cardiovascular mortality than did those treated with diet alone, indicating that the severity of diabetes contributes to the risk of cardiovascular mortality [148,149].

Recent extensive evidence confirms the excess risk of cardiovascular mortality in diabetic patients. Data from the intensive blood-glucose treatment arm of the United Kingdom Prospective Diabetes Study (UKPDS) examined the reasons for death in patients with newly diagnosed type 2 diabetes over a 10-year follow-up period. The UKPDS showed that 8.4% of type 2 diabetic patients died of either fatal MI or sudden death, whereas mortality associated with other disease was relatively very low [150]. Data from an age- and sex-matched group in the Framingham Study show that for nondiabetic individuals the equivalent mortality rate over 10 years is only 4% [151].

Women in general have a lower unadjusted risk of CHD than do men. In many studies, rates of CVD in women with diabetes equal or exceed those in men [152–154], although not all studies have demonstrated this relationship [155,156]. More research is also needed to determine whether this is true for both T1DM and T2DM. The Wisconsin population-based study reported a similar risk ratio in both T2DM men (2.4) and women (2.2) versus nondiabetic persons. Nevertheless, in T1DM women the

risk ratio (13.5) was significantly higher than that in T1DM men (9.1) [157]. The reason for the accelerated atherogenesis among diabetic women is not completely understood, but it may relate to hyperglycemia itself since this phenomenon is seen both in young-onset T1DM patients [158] and in older T2DM patients [104]. It may also relate, at least in part, to more severe lipid and lipoprotein abnormalities, particularly elevated levels of triglycerides and reduced levels of HDL, among diabetic women [159,160]. A recent study [161] suggests greater impairment of endothelial function associated with T2DM in women than in men. The role of hyperinsulinemia and insulin resistance is important in understanding the link between female gender and risk of CVD in diabetic patients. Insulin resistance is associated with lower estrogen and higher androgen levels. Premenopausal women with insulin resistance or diabetes do not benefit from the protective effects of menstruation experienced by women without these conditions [162]. In addition, the magnitude of increased risk of reinfarction and fatality rate following an acute MI among diabetic patients compared with nondiabetic patients was greater in women than in men [163]. Several studies have noted that CVD mortality in diabetic patients was related to age at the onset of diabetes or to duration of diabetes [145–147,164]. In the Diabetes Epidemiology Research International Study of young-onset T1DM patients, cardiovascular deaths were relatively few during a follow-up of 8–15 years, although significantly increased as compared with the rates in the background population [165].

Excess mortality, CVD mortality in particular, extends beyond the limits of diabetes to IGT. Studies in the United Kingdom, in Bedford [166] and in Whitehall, London [167], have all consistently shown increased mortality at the upper end of the blood glucose distribution before T2DM is manifest. This is in agreement with the findings of Uusitupa et al. [168] who showed that a considerable number of T2DM patients had already suffered an MI before the time of diagnosis of their diabetes. Similar findings were also observed in the Pacific Island populations where CHD is much less common than in Europid populations [169].

Mortality and case-fatality in AMI

There are wide differences in the age-adjusted incidence of fatal CHD in T2DM patients between populations: the highest rates were in Framingham [170] where they were 4% per year for men, but the rates were only 1% per year in the Chicago Heart [171] and MRFIT [172] studies. In Europe, the CHD incidence varied from 2.6% per year in Finland [173] and 2.2% in the Schwabing cohort [174], to 1 to 1.4% per year in the United Kingdom [175] and in another study in Finland [140] and 0.4% per year in the Paris Prospective Study in France [176]. Prospective studies from Japan have reported very low mortality from CHD in both T2DM and T1DM [165,177], corresponding to the general rates in Japan. Also in Pima Indians who have the highest prevalence of T2DM in the world, mortality from CHD

is not particularly high [178]. Nevertheless, the most recent information on total and CVD mortality among the Native Americans in the Strong Heart Study has revealed that currently American Indian populations have higher CVD mortality rates than in other ethnic groups in the United States [153].

A number of studies have demonstrated that diabetes mellitus negatively influences the survival after MI, including increased rates of reinfarction, congestive heart failure, and death [112,179–187]. The largest population-based study of the impact of diabetes on mortality after the first MI was the FINMONICA Study [185]. The 1-year case-fatality rate for first MI (including prehospitalization mortality) was 45% in diabetic men and 39% in diabetic women. These case-fatality rates were significantly higher than rates in nondiabetic male and female subjects (38 and 25%, respectively). Furthermore, diabetic patients were more likely than nondiabetic patients to die from sudden cardiac death before reaching hospital. In unstable angina pectoris or non-Q-wave in-hospital MI, the presence of diabetes increases the risk of inhospital MI, complications of MI, and mortality [186]. In the OASIS Registry, a six-nation study of unstable angina and non-Q-wave MI, diabetes independently increased the risk of death by 57% [187]. In the SHOCK Trial of revascularization for MI complicated by cardiogenic shock, the relative risk of death for patients with diabetes was 1.36 compared with that of nondiabetic patients [188].

There also seems to be a differential gender-related effect regarding the type of diabetes on case-fatality in AMI. Data from the GISSI-2 Study have shown that in men, both T1DM and T2DM were associated with moderately higher mortality rate after MI compared with nondiabetic men [183]. In women, diabetes was a strong risk factor for death following an MI. In the Framingham Study [163], which included a much higher proportion of women than men taking insulin (27% vs. 15%), the relative risk of fatal CHD was higher for women than men. In men, the presence of diabetes may lead to an overall decreased survival rate independent from the type of diabetes, whereas in women, T1DM is uniquely associated with major alterations in cardiovascular function that have a strong impact on mortality after MI.

Reviewed by Jacoby and Nesto [189], the reasons for the increased case-fatality in AMI in diabetic patients still remain debated. Some of the studies suggested that a higher prevalence of other risk factors (hypertension, hyperlipidemia, extensive coronary artery disease, and advanced age) or higher degree of left ventricular damage after infarction may explain the higher mortality rate in diabetic patients. Conversely, other studies [190] indicate that the detrimental effect of diabetes on survival is most evident in patients whose baseline risk factor profile would indicate a relatively low risk of death after MI, thus suggesting that pathophysiologic derangements accompanying diabetes that apparently do not affect the clinical status of the patients may play a subtle but critical role as they reduce

survival after MI. A study from the community-based AMI register in Finland demonstrated that there were no differences in cardiac enzyme or ECG findings between diabetic and nondiabetic patients who had their first AMI [184]. Thus, there was no evidence that the size of AMI is larger in diabetic than nondiabetic subjects. It is known that AMI is often associated with an acute hyperglycemia. This may be particularly aggravated in diabetic AMI patients leading to various metabolic and cardiac problems during the first 1–2 weeks after AMI. The DIGAMI Study suggests benefit from glucose lowering post-AMI [191], and so this problem may be reversible. The current evidence has also revealed that diabetic patients without previous MI have as high a risk of developing MI as nondiabetic patients with previous MI [141], although these findings have not been supported by all more recent, larger, studies [192,193]. It is possible that this effect is more pronounced in women than in men; thus studies comprising only men may not have reconfirmed this initial finding from a study where both sexes were included.

Risk factors for CHD in diabetic patients

Several studies have examined risk factors for CHD in T2DM patients, whereas little population-based prospective data are available on the risk and determinants of CHD in T1DM. The traditional risk factors, such as cigarette smoking, serum cholesterol, or BP, play an important role in the development of CHD in diabetic patients [172], but they explain only a part of the excess risk of ischemic heart lesions in diabetes [194–196]. The greater the number of coronary risk factors, the higher the susceptibility to CHD whether diabetic or not [140,166,172,173]. Hyperglycemia was found to be predictive of CHD death for T2DM in several studies [140,173,175,194,195]. The recently published results from the Nurses' Health Study indicated duration of T2DM as an important factor associated with increased risk of death from all causes and fatal CHD [164]. Compared with those in nondiabetic persons, the multivariate relative risks of fatal CHD across categories of diabetes duration (5, 6–10, 11–15, 16–25, >25 years) were 2.75, 3.63, 5.51, 6.38, and 11.9 ($p < 0.001$ for trend), respectively. The combination of prior CHD and a long duration of clinical diabetes (i.e., >15 years) was associated with a 30-fold (95% CI 20.7–43.5) increased risk of fatal CHD [164]. These results need to be confirmed by other studies.

Serum cholesterol level has been found to be particularly important in predicting cardiovascular mortality [196]. In men with and without diabetes, CHD death rates increased markedly with increasing cholesterol levels. At every level of serum cholesterol, however, the CHD death rate was several times higher for diabetic than nondiabetic men, and the increase in absolute CHD mortality rate with higher serum cholesterol level tended to be disproportionately greater for diabetic men than for nondiabetic men [172].

The lipid profiles predictive of cardiovascular death were assessed in the Paris Prospective Study [197]. The relationship between baseline triglyceride levels alone was clear: individuals with the lowest baseline triglyceride levels had the lowest risk of death from CHD during 15 years of follow-up. Conversely, individuals with CHD had the highest triglyceride levels [197]. Also previous cross-sectional findings from the WHO Multinational Study suggested that triglycerides were a stronger predictor of CHD and PVD in several countries than was total cholesterol [198]. Adults with diabetes do not have total cholesterol or low-density lipoprotein (LDL) cholesterol concentrations that are significantly increased compared with the general population [199]. However, significantly more patients with diabetes have low HDL-C levels and elevated triglyceride levels compared with individuals without diabetes. Thus, lipid abnormalities, although not necessarily hypercholesterolemia, contribute to the prediction of CHD [140,173,174,197]. Elevated levels of triglyceride-rich lipoproteins lower HDL levels by promoting exchanges of cholesterol from HDL to very low density lipoprotein (VLDL) via cholesteryl ester transfer protein [200]. Diabetic persons with CHD more commonly have the combination of elevated triglycerides and low HDL than elevated total and LDL cholesterol levels [201].

Risk factors for CHD related to increased triglyceride concentrations include an increase in postprandial accumulation of remnant lipoproteins, which form highly atherogenic particles [202,203]. Erkelens [204] has summarized available data on the altered composition of lipoproteins and lipids, so-called diabetic dyslipidemia, in patients with T2DM. Thus, diabetic dyslipidemia is characterized by (1) elevated levels of triglyceride; (2) normal levels of total cholesterol and LDL-C; (3) reduced levels of HDL-C; (4) elevated levels of apolipoprotein B; (5) a preponderance of small, dense LDL particles; and (6) increased levels of cholesterol-rich VLDL [204].

Central fat distribution appears to be one of the prominent indicators of CHD risk in the Paris, Gothenburg, and Framingham studies [197,205,206]. Also, android fat distribution independently of BMI contributes to the development of T2DM. This is particularly striking in women, as demonstrated in the Gothenburg Study [207]. Also in studies from Iowa [208] and Mauritius [209] the risk of developing diabetes increased with BMI as well as with the waist-to-hip ratio; the highest risk was observed for the highest combined tertiles. Björntorp [210] has suggested that the intra-abdominal tissue, particularly the portion drained by the portal circulation, has an exceedingly sensitive lipomobilization capacity. This results in high portal free fatty acid concentrations, which in turn generate through hepatic regulation hyperinsulinemia, hyperglycemia, and T2DM. This is associated with a cluster of metabolic abnormalities defined as the insulin resistance syndrome. To explain what makes fat accumulate intra-abdominally rather than subcutaneously, Björntorp suggested a number

of possibilities that involve, besides genetic predisposition, endocrine perturbations, which could, for example, affect glucocorticoid and androgen levels. These perturbations can occur as a consequence of certain modern lifestyle factors such as stress, smoking, alcohol consumption, lack of physical activity, and the excessive intake of saturated fat.

Since the first suggestions of the insulin–atheroma relationship in the 1960s [211,212] there have been many clinical, experimental, and epidemiologic studies addressing this question. Insulin may directly promote atherosclerosis [213]. Although insulin correlates with a number of cardiovascular risk factors, such as BMI, body fat distribution, serum triglycerides, and HDL cholesterol, epidemiologic studies of the insulin–CHD relationship have provided inconsistent findings, both cross-sectionally and longitudinally. Moreover, populations that are clearly hyperinsulinemic such as Pima Indians, Naurans, Polynesians, etc., do not have a particularly high mortality from CHD [178,214–217]. Data from the Multiple Risk Factor Intervention Trial [218] demonstrated that insulin appears to contribute to cardiovascular risk in persons with apolipoprotein E 3/2 phenotype but does not explain the increased risk seen in these subjects. The authors suggested that this new finding, if confirmed, may throw further light on the role of insulin in atherosclerosis.

Long-term hyperglycemia may explain a large proportion of excessive cardiovascular mortality among T2DM patients not explained by classical coronary risk factors [140]. In addition, it was recently hypothesized that increased plasma and tissue glucose levels may be one important source of the increased oxidative stress seen in diabetic patients, which through various metabolic mechanisms could predispose to atheroma [73].

Albumin excretion rate has also been shown to be significantly associated with CHD morbidity after taking into account the confounding effects of raised BP and other coronary risk factors [219–221]. Also Nielsen et al. [222] has noted that the prevalence of CVD increases with increasing albumin excretion in T2DM. It was shown that the simultaneous occurrence of hyperinsulinemia and microalbuminuria is a strong predictor of CHD events in elderly nondiabetic people [223]. Several earlier studies performed among T1DM patients also observed a substantial increase in mortality from, and incidence of, CHD in those with nephropathy compared with T1DM patients without nephropathy [224,225]. In the Finnish cohort of childhood-onset T1DM patients the risk of CHD was high, about 3–4% after 20–33 years of follow-up when the patients were aged 19–49 years [158]. The risk of CHD was 10-fold in those who had developed nephropathy compared with those without nephropathy, and increased with increasing duration of nephropathy.

Prothrombotic and fibrinolytic factors act in concert to maintain hemostasis. Plasminogen activator inhibitor 1 (PAI-1), an enzyme needed to lyse a thrombus once formed, is synthesized in endothelial cells, vascular smooth muscle cells, adipose

tissue, and the liver. Insulin resistance is associated with a shift toward the prothrombotic state and highly correlated with an increased risk of MI [226]. In an analysis of the Framingham population, levels of PAI-1 were measured in men and women with normal glucose tolerance, and those with IGT or previously undiagnosed diabetes [227]. In the latter two groups, levels of PAI-1 were consistently twofold higher than in the group with normal glucose tolerance. This finding suggests that these persons have a reduced ability to eliminate clots once they have formed.

The ARIC Study examined the association of traditional and nontraditional risk factors with incidence of CHD in adults with diabetes [228]. After adjustment for hypertension, smoking, total cholesterol level, and low HDL cholesterol level, levels of albumin, fibrinogen, and von Willebrand factor, factor VII activity, and leukocyte count were predictors of CHD among persons with diabetes. The authors suggested that these associations may reflect the underlying inflammatory reaction or microvascular injury related to atherosclerosis and a tendency toward thrombosis or common antecedents for both diabetes and coronary heart disease [228]. C-reactive protein has been shown to have predictive value in nondiabetic populations [229] but has not been well studied in persons with diabetes.

Similarly to hypertension, it has been suggested that an activation of the renin–angiotensin system may play a role in the pathogenesis of CHD [230]. Both T1DM and T2DM patients with abnormal albumin excretion have increased plasma angiotensin-I-converting enzyme (ACE) concentration [231]. Several studies have evaluated the insertion (I)/deletion (D) polymorphism of the ACE gene in association with the risk of MI and severe CHD in nondiabetic subjects and T2DM patients with conflicting findings [232,233].

Stroke and cerebrovascular diseases

Incidence and mortality

Diabetes mellitus magnifies the risk of cerebrovascular morbidity and mortality [162,234–241] (Table 69.1). The Framingham Study was one of the earliest to demonstrate an increased morbidity and mortality from cerebrovascular disease in patients with diabetes. Similar conclusions have been drawn from most, although not all, subsequent studies of patients with T2DM [235–240]. In a prospective study from Finland with a follow-up of 15 years, diabetes was the strongest single factor for stroke in a multivariate analysis (relative risk for men 3.4 and for women 4.9) [241]. Diabetes is a prominent risk factor for ischemic but not hemorrhagic stroke [241,256,257]. However, the recent joint report from the Honolulu Heart Program and the Framingham Study suggested that an increased risk of hemorrhagic stroke may also exist in T2DM [237].

Ischemic cerebrovascular disease accounts for about 80% of all strokes [258], but the female-to-male mortality ratio differs for stroke subtypes by ethnicity and age [259]. Diabetes mellitus is a definite independent risk factor for atherosclerosis and atherothrombotic brain infarction [240,247,260,261]. In the Framingham Study the incidence of atherothrombotic cerebral infarction for both sexes aged 45–74 years was greater by a factor of 2.5–3.5 in diabetic men that in nondiabetic subjects. Among the diabetic cohort, ischemic cerebral infarction comprised 88% of stroke events, 8% were subarachnoid or intracerebral hemorrhages and the rest of the strokes were of unknown type. Diabetes mellitus may also cause microatheroma in small vessels, such as lenticulostriate arteries, leading to lacunar stroke, one of the most common subtypes of ischemic stroke. Lacunar stroke is a unique subtype and requires specific clinical and radiological features for diagnosis. The presence of diabetes mellitus was associated only with symptomatic cerebral infarcts but not with silent infarcts [262], which are five times as prevalent as symptomatic brain infarcts in the general population [263].

A negative correlation has been reported between diabetes, especially T1DM, and aneurysmal subarachnoidal hemorrhage (SAH) [256]. While diabetes is one of the major risk factors for stroke in general, patients with aneurysmal SAH have a lower or equal prevalence of diabetes mellitus than does the general population. In particular, T1DM is rarely present prior to aneurysmal rupture [256]. However, there are also opposite opinions, since two studies claim that diabetes is closely associated with SAH and stroke [264,265]. Stroke patients with diabetes, or with hyperglycemia in the acute stage of stroke, have a higher mortality rate, worse neurologic outcome, and more severe disability than did those without [260–269]. The presence of diabetes, however, did not influence the outcome of parenchymatous hemorrhage or SAH [264,270]. There is insufficient information on the association of diabetes mellitus and radiologically confirmed SAH [271]. In a recent study, there was no difference in the presence of diabetes among SAH patients and controls [272]. Finland has one of the highest incidences of SAH [273]. During 1990–1998, 5630 first stroke events were registered in a community-based stroke register [274]. The subtype of the stroke was ischemic in 81%, hemorrhagic in 12%, and subarachnoid hemorrhage in 7% of the cases. The percentage of CT, MRI, angiography, or autopsy was 98%. The number of patients with diabetes was 1148 (20%). Of these, 19% were on insulin therapy and 81% were on diet alone or oral drug therapy. SAH was less common in patients with diabetes (1.0%) than patients without diabetes (8.2%, $p < 0.00001$).

There is much less information concerning the risk of stroke in T1DM. Deckert et al. [144] studying a group of patients who had had T1DM for more than 40 years, reported a 10% cumulative incidence of stroke and 7% mortality from stroke. The World Health Organization Multinational Study

Table 69.1 Relative risk of stroke in the diabetic population

	Relative risk in diabetic patient
USA, 1970 [242]	Hospitalized patients ×1.4 aged 45–69 years
Seal Beach and Chicago, USA, 1972 [243]	×1.7 males; ×2.8 females
Jerusalem, Israel, 1973 [244]	Hospitalized patients ×6 in 5th decade; ×3 in 6th decade; ×2 after age 60
Chicago, USA, 1974 [245]	×1.3 in elderly patients receiving financial assistance
Hawaii, USA, 1980 [246]	×2.0
Tilsburg, The Netherlands, 1982 [247]	Hospitalized patients ×2.2
Framingham, USA, 1983 [248]	Males ×4 in 5th and 6th decade; ×1 in 7th decade; females ×1 in 5th decade; ×4 in 6th decade; ×3 in 7th decade
Rochester, USA, 1983 [249]	×1.4 in population with median age of 75 years
Monroe Co., USA, 1983 [250]	Hospitalized patients ×3.3
USA, 1987 [251]	×4 45–64-year-olds; ×2.5 65–74-year-olds
Sweden, 1987 [252]	×6 males; ×13 females
USA, NHANES, 1990 [239]	×2.5 males; ×2.5 females; 35–74-year-olds
Framingham, USA, 1991 [236]	×1.4 males; ×1.7 females; 55–84-year-olds
MRFIT, USA, 1993 [253]	×3.8 in males
Oslo, Norway, 1995 [254]	×7.9 males; 40–49-year-olds
Sweden, 1995 [255]	×4.4 males; ×5.1 females; 35–74-year-olds
MRFIT, USA, 1998 [238]	×1.8 males; ×2.1 females
USA, 2002 [237]	population-based study ×2.1 in Hawaii and ×3.6 in Framingham; only men age-adjusted for thromboembolic stroke; ×4.9 for hemorrhagic strokes in Framingham

of vascular disease in diabetes has indicated an overall raised cerebrovascular mortality in patients with T1DM, but with considerable variation between countries [275].

The data from the large nationwide cohort of Finnish childhood-onset T1DM patients showed that by the age of 50 years, and after 20–40 years duration of diabetes, the risk of stroke was equally high as that of acute CHD [158]. Also, the risk of stroke was equally common in both sexes. Previously, many T1DM patients who also had other risk factors for stroke (e.g. hypertension, smoking, dyslipidemia) had a high probability of dying relatively young from diabetic renal diseases or CHD, and so the number of T1DM patients surviving until "stroke risk age" (older than 65 years) has thus far been small. It is likely that improved treatment for hypertension and better blood glucose control will change this situation markedly, and stroke will become an important late complication of T1DM in the future.

Risk factors for stroke in diabetic patients

In a Finnish study [276], fasting and 2-h glucose, a HbA1c duration of diabetes, and atrial fibrillation were the baseline variables predicting both fatal and nonfatal stroke events in T2DM patients during a 3.5-year follow-up. The association between duration of diabetes and risk of stroke was reported by these authors and also by other prospective studies from Finland [158,241]. The risk factors for stroke were the same for diabetic and nondiabetic subjects. Others have not found a significant relationship between ischemic stroke and diabetes duration,

fasting glucose level, and serum HDL-cholesterol [277]. The Pima Indian Study did not find any relation between duration of T2DM and the risk of fatal stroke [278]. Results from the Honolulu Heart Program indicated that the serum glucose level at baseline was an independent risk factor for all cerebrovascular accidents and for thromboembolic strokes [237]. In a study from Oslo, nonfasting serum glucose was a risk factor for stroke mortality only in men with BMI above the median value, and only in univariate but not in multivariate analysis [254].

Several studies have provided sufficient evidence to indicate that hypertension and diabetes mellitus have direct effect on the occurrence of moderate to severe atherosclerotic stenosis of extracranial and intracranial arteries [279,280]. Furthermore some clinical series have suggested that patients with single lacunes may represent an entity different from those with multiple lacunes in that only the latter group have an increased frequency of arterial hypertension and diabetes mellitus [281,282]. However, in comparison with nonhemorrhagic lacunar stroke, patients with hemorrhagic lacunar stroke are less likely to have diabetes mellitus [283].

BP is a well-known risk factor for stroke in both types of diabetes [275], and the UKPDS trial suggested that controlling blood pressure in patients with T2DM reduced the stroke risk although not the risk of AMI [284]. Diabetic subjects have higher systolic BP than does the general population, particularly females [5,11,240,241,285]. It is suggested that diabetes may enhance the risk of stroke even in the absence of increased BP. In the nondiabetic population, there is a 40% increase in

stroke risk and a 25% increase in CHD risk with an elevation of 6 mmHg in excess of 75 mmHg diastolic BP. Diabetes increases the risk of both conditions by a factor of 2 or 3, and in diabetic subjects hypertension augments these risks [286]. Tuomilehto et al. [241] did not find evidence for an interaction between BMI, diabetes, and BP in a prospective study of stroke in a random population sample. There were neither additive nor multiplicative effects between diabetes and other CVD risk factors. Thus, it is unlikely that the risk of stroke associated with diabetes would be restricted to a particular subgroup, such as obese or hypertensive subjects. Moreover, it is possible that a part of the increased risk of stroke seen in hypertensive subjects is related to abnormalities of glucose metabolism, which are a common correlate of hypertension, particularly in the elderly [241,287,288].

It has been noted that the relative significance of risk factors for stroke varies with age and sex [289]. Hypertension, BP, smoking, hematocrit, and left-ventricular hypertrophy are strongly associated with stroke in patients younger than 65 years. Diabetes seems to be a stronger risk factor for stroke in females than in males [255,290]. Diabetes adversely affects cerebrovascular arterial circulation, akin to its effects in the coronary and lower extremity vasculature. Patients with diabetes have more severe extracranial atherosclerosis [291].

Besides being a risk factor for stroke, it has been shown that diabetes in the aftermath of the stroke event increases regional brain damage due to acute vascular insufficiency [292,293] and may have deleterious effects in both the short- and long-term prognosis of stroke [266–269,294]. It was shown that hyperglycemia directly increases regional brain damage due to acute vascular insufficiency [292]. Some studies have claimed, however, that neither a history of diabetes nor the glucose levels on admission are related to the outcome in an acute stroke event [295–300]. A number of studies have investigated whether diabetes has influence on the volume of damaged brain tissue in patients with stroke, as newer imaging methods have made the comparisons of stroke size possible. Most studies using computed tomography [267,268,300] and autopsy [301] have not found differences in the size of cerebral infarction between patients with and without diabetes mellitus.

There are at least three possible explanations for the worsening of stroke damage in the presence of hyperglycemia [302]. First, under the hypoxic conditions caused by a stroke, glucose is anaerobically metabolized to lactic acid, and the resultant cerebral intracellular and extracellular acidosis causes damage to neurones, glial, and vascular tissue. The effects of glycemia may also differ at different anatomical sites. In the center of an infarct, excess glucose will worsen damage, whereas in the surrounding ischemic area, an increase in glucose level may lessen damage. Secondly, under hyperglycemic and hypoxic conditions the extracellular concentration of amino acids is increased because of excessive release combined with failure of energy-dependent re-uptake that would normally result in detoxification of glutamate and aspartate. A third theory is that with ischemia and hyperglycemia, together with neuronal hyperstimulation, intracellular calcium concentration increases, which may cause neuronal damage.

Excessive alcohol intake may increase the risk for stroke among patients with diabetes [303,304]. In addition, the Gothenburg population cohort study of mostly T2DM showed that alcohol combined with diabetes are important risk factors for cerebral infarction [252].

The increased incidence of and mortality from stroke in patients with T1DM is strongly related to the development of diabetic nephropathy [158,305]. The presence of nephropathy increases the stroke risk up to 10-fold compared with T1DM patients without nephropathy, and the stroke risk increases with increasing duration of nephropathy [158]. When proteinuria develops, not only is there an increase in systolic and diastolic BP but also an increase in von Willebrand factor, fibrinogen, platelet adhesiveness and number, and stimulated levels of tissue plasminogen activator and plasminogen activator inhibitor [305,306]. No evidence associates background diabetic retinopathy or proliferative retinopathy with an increased prevalence of stroke in T1DM [307]. Only one study has shown an increase in the relative risk of nonembolic ischemic stroke in diabetic subjects with retinopathy [308]. However, that study was unable to distinguish T1DM and T2DM subjects and duration of diabetes was not taken into account.

Asymptomatic hyperglycemia and CVD risk

It has been known for quite some time that individuals with overt diabetes have an increased risk for CVD, but the fact that subjects with asymptomatic diabetes or hyperglycemia are also at high risk for the development of CVD has been recognized only recently. Earlier studies such as the International Collaborative Group [309] in 1979 did not show consistent evidence for a threshold or graded association between asymptomatic hyperglycemia and CHD. In 1985, Epstein [310] reviewed 13 cohort studies that had studied postchallenge glucose and CHD; the results were conflicting.

Over the past decades, the prevalence of diabetes has increased markedly worldwide. Only around 1980, the National Diabetes Data Group (NDDG) [311] and WHO [312,313] formulated criteria for diagnosing diabetes based on glucose levels 2-h after a 75-g oral glucose load. The near-universal adoption of these diagnostic criteria has created order out of the confusion in the diagnostic criteria for diabetes and stimulated the interest in studying outcomes related to different categories of hyperglycemia. Now, after about two decades from the adoption of standard criteria for diabetes and glucose

intolerance, epidemiologic evidence has been accumulated showing that asymptomatic diabetes, as well as hyperglycemia in the nondiabetic range was associated with the increased risk of CVD. Coutinho et al. recently made a metaregression analysis of the data published between 1966 and 1996 from 20 studies comprising 95,783 individuals (94% male) followed on average for 12.4 years, and demonstrated that the progressive relationship between glucose levels and CVD risk extends below the diabetic threshold [314]. In data from the 23-year follow-up of the Paris Prospective Study of 7018 men, aged 44–55 years at baseline, Balkau et al. found that the relationship of fasting and 2-h post load glucose with mortality from all-causes and CHD were curvilinear, and that the increased risks already became apparent at the upper levels of the nondiabetic glucose distribution [315]. Results from a 22-year follow-up of nondiabetic Norwegian men (aged 40–59 years) showed a multivariate adjusted relative risk of 1.4 (95% CI 1.0–1.8) for CVD mortality in men with fasting whole blood glucose $>4.7 \, \text{mmol} \, L^1$ compared with $<4.7 \, \text{mmol} \, L^1$ [316]. An increased risk of developing CHD associated with the highest quartile of normal fasting glucose distribution was also observed in Australian nondiabetic women, but not in men [317].

Increasing evidence has been accumulated on the importance of hyperglycemia after an oral glucose challenge as an independent risk factor for CVD. In the Chicago Heart Study of 11,554 White men and 666 Black men aged 35–64 years, asymptomatic hyperglycemia ($>11.1 \, \text{mmol} \, L^{-1}$) 1 h after a 50-g glucose load showed increased CVD mortality in both White and Black men [318]. The 23-year follow-up of the Honolulu Heart Program among 8006 Japanese American middle-aged men also suggested an increasing risk gradient between 1-h postload glucose and CHD [319]. In the Hisayama Study, the multivariate adjusted relative risk for the incidence of CHD and stroke in Japanese aged 40–79 years was 1.9 (95% CI 1.2–3.2) for subjects with IGT compared with those who had a normal glucose tolerance [320].

In the late 1990s, a new surge of interest to study the relationship between asymptomatic hyperglycemia and the risk of CVD developed following the 1997 revision of diagnostic criteria for diabetes and milder degrees of hyperglycemia by the American Diabetes Association. In the Funagata diabetes study of a Japanese cohort aged 40 years or over, IGT but not impaired fasting glycemia (IFG) was associated with increased CVD mortality [321]. In the Hoorn study in the Netherlands in subjects with no prior history of diabetes, 2-h postload glucose proved to be a better risk predictor of CVD mortality than does fasting glucose or HbA1c [322]. Pooled longitudinal data from Mauritius, Fiji, and Nauru showed that isolated postchallenge hyperglycemia ($>11.1 \, \text{mmol} \, L^{-1}$) with a nondiabetic fasting plasma glucose ($<7.0 \, \text{mmol} \, L^{-1}$) doubled the CVD mortality risk [323]. Similar results were also observed in older Californian women [324]. A recent analysis of the data from

US Second National Health and Nutrition Survey, including 3092 adults aged 30–74 years, revealed that subjects with IGT and undiagnosed diabetes defined by isolated postload hyperglycemia had 40% higher CVD mortality rates compared with those with a normal glucose tolerance [325]. Thus, there is no doubt that the risk of CVD starts to increase much before the development of fasting hyperglycemia. A 20-year follow-up of 117,629 women aged 30–55 years in the Nurses' Health Study in the United States revealed that the risk of incident nonfatal MI and stroke started to increase 15 years before a clinical diagnosis of diabetes [326]. The multivariate adjusted relative risk for MI or stroke was 2.4, 3.2, and 3.6, respectively, for female nurses 15 years, 10–14.9 years, and <10 years before the onset of diabetes, in comparison with those who remained nondiabetic throughout the study.

The most convincing evidence of increased CVD risk related to asymptomatic hyperglycemia was provided by the DECODE (Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Europe) Study. In this study, data from 10 prospective European cohort studies including 15,388 men and 7,126 women aged 30–89 years were collaboratively analyzed [327,328]. Multivariate Cox proportional hazard analyses showed that the risk for death from all-cause, CVD, CHD, and stroke significantly increased in subjects with asymptomatic diabetes defined according to either the fasting plasma glucose $>7.0 \, \text{mmol} \, L^{-1}$ or the 2-h postload plasma glucose $>11.1 \, \text{mmol} \, L^{-1}$. People with IGT also had an increased risk of death compared with those whose glucose tolerance was normal, but subjects with IFG did not have increased risk of death [327,328] (Table 69.2). Furthermore, the DECODE Study revealed that elevated 2-h glucose was a better predictor of mortality from all-cause, CVD, and CHD than did elevated fasting glucose alone [327,328]. A high 2-h glucose concentration was found to be associated with an increased risk of death, independent of the level of fasting blood glucose, whereas mortality associated with the fasting glucose concentration depended on the simultaneous level of 2-h glucose [327] (Table 69.3). Addition of 2-h glucose to a model based on fasting glucose improved the prediction (all p values <0.05, except for stroke). Conversely, fasting glucose did not add any further information once the 2-h glucose concentration was in the model (all p values >0.10) [327]. The largest absolute number of excess deaths was observed in subjects with IGT, especially those with IGT but normal fasting glucose, reflecting the fact that this category is the most prevalent abnormality in glucose regulation [327,328].

The observations from the DECODE Study on mortality related to 2-h glucose versus fasting glucose have also been extended to the prediction of the risk of serious incident CHD events (CHD death and nonfatal MI) based on five Finnish DECODE Study cohorts [329]. These results confirmed that in subjects without a prior history of diabetes the association of 2-h glucose with CHD incidence is graded and independent,

Table 69.2 Multivariate adjusted hazard ratios for deaths from cardiovascular diseases (CVD), coronary heart diseases (CHD), stroke, and all-cause according to the fasting and the 2-h glucose criteria: the DECODE Study

| | Plasma (whole blood) glucose categories (mmol L^{-1}), subjects not known as diabetic | | | | |
| | Fasting glucose criteria* | | 2-h glucose criteria† | | |
	IFG 6.1–6.9 (5.6–6.0)	Diabetes ≥7.0 (6.1)	IGT 7.8–11.0 (6.7–9.9)	Diabetes ≥11.1 (10.0)	Known diabetes†
CVD	1.09 (0.90–1.30)	1.48 (1.15–1.91)	1.34 (1.14–1.57)	1.55 (1.20–2.01)	1.96 (1.62–2.37)
CHD	1.07 (0.83–1.39)	1.43 (1.02–2.02)	1.28 (1.02–1.59)	1.64 (1.18–2.28)	1.94 (1.51–2.50)

§Compared with the models in Table 69.1, with only the fasting glucose criteria, 2 df.

Figure 69.1 Cumulative survival curves for incidence of coronary heart disease (a) and for cardiovascular mortality (b) according to the glucose categories defined by both fasting and 2-h plasma glucose criteria. The cumulative survival are estimated from Cox proportional hazards models and adjusted for age, cohorts, sex, body mass index, blood pressure, serum cholesterol, and smoking. Normal, fasting plasma glucose <6.1 mmol L^1 and 2-h plasma glucose <7.8 mmol L^1; IFG, impaired fasting glycemia only; IGT, impaired glucose tolerance only; IGR, impaired glucose regulation (IFG and IGT); DMF, undiagnosed diabetes by fasting glucose criteria alone (fasting plasma glucose ≥7.0 mmol L^1 and 2-h plasma glucose <11.1 mmol L^1); DMP, undiagnosed diabetes by 2-h postload glucose criteria alone (2-h plasma glucose ≥11.1 mmol L^1 and fasting plasma glucose <7.0 mmol L^1); DMC, undiagnosed diabetes by both fasting and 2-h glucose criteria combined (fasting plasma glucose ≥7.0 mmol L^1 and 2-h plasma glucose ≥11.1 mmol L^1); known DM, previously diagnosed diabetes. (For a color version of this figure, please see color plate section.)

and that 2-h glucose is superior to fasting glucose in assessing the risk of future CHD events (Figure 69.1). Thus, the DECODE Study unequivocally confirmed that asymptomatic postchallenge hyperglycemia independently increases cardiovascular morbidity and mortality and is a better predictor of the events than fasting hyperglycemia.

Whether postchallenge hyperglycemia is a true risk factor for CHD or merely a reflection of a high-risk phenotype remains to be determined [330]. Postchallenge plasma glucose concentrations are more strongly correlated with a variety of risk factors than are those of fasting plasma glucose in nondiabetic subjects, including central obesity, low-grade inflammation, and endothelial dysfunction [331]. It also remains unclear as to whether postchallenge hyperglycemia and postprandial hyperglycemia are similar or distinct characteristics. One study has suggested that mild-to-moderate mealtime hyperglycemia is an independent risk factor for increased IMT [332]. In a cohort at risk for diabetes, postchallenge glucose and glycemic excursions were found to be more strongly associated with carotid IMT than fasting glucose or HbA1c level [333]. More recently, Ceriello et al. has shown an independent and cumulative deleterious effect of postprandial hypertriglyceridemia and hyperglycemia on endothelial function and suggested that oxidative stress is the common mediator through which they exert such effects [87].

These findings may be important especially in the elderly population because postchallenge glucose levels increase to a much greater extent with advancing age than fasting glucose [324,334]. In the DECODE population, the prevalence of isolated postload hyperglycemia, that is, 2-h plasma glucose $\geq$11.1 mmol L^{-1} and fasting plasma glucose <7.0 mmol L^{-1}, was 0.7% in people 49 years or younger and 4.6% in those older than 70 years. In contrast, the prevalence of isolated fasting hyperglycemia, that is, 2-h plasma glucose <11.1 mmol L^{-1} and fasting plasma glucose $\geq$7.0 mmol L^{-1}, in these two age groups was 1.3 and 2.3%, respectively [335]. Fasting glucose levels in this aspect can be compared with diastolic blood pressure that beyond middle age does not rise with aging, whereas systolic blood pressure does and also is a stronger predictor of cardiovascular events [336]. With conclusive evidence, the guidelines for the treatment of hypertension have been modified to emphasize the importance of systolic blood pressure [14]. These recommendations are, however, more firmly based on intervention studies, and not only on epidemiologic evidence. The need for similar reassessment regarding postchallenge or postprandial versus fasting glucose, and for evaluating possible benefit of treatments focused on postprandial hyperglycemia, is required, especially in the elderly population. The guidelines on diabetes, prediabetes and cardiovascular disease published by the European Society of Cardiology [337] also emphasize the importance of testing all patients with CVD with an oral glucose tolerance test in order to detect people who have previously undiagnosed diabetes.

Atherogenesis, coronary heart disease and insulin resistance syndrome in diabetes

Barak Zafrir and Jorge Plutzky

Brigham and Women's Hospital, Boston, MA, USA

Key points

- Type 2 diabetes (T2DM), the insulin resistance that typically accompanies T2DM, and the constellation of abnormalities that define the metabolic syndrome all promote atherosclerosis and its complications.

- Significant molecular, cellular and clinical overlap exists in terms of the pro-atherosclerotic forces found in T2DM and the metabolic syndrome, including pathways such as inflammation.

- Both T2DM and atherosclerosis involve long subclinical phases prior to the manifestation of clinical disease, with attention focused on mediators and markers that may allow earlier identification and intervention. The metabolic syndrome, comprised of risk factors for developing diabetes and cardiovascular disease (CVD), can be considered as one such tool although its practical utility and meaning as a diagnostic and management tool remain controversial. Prediabetes as a condition may overlap with the metabolic syndrome.

- Specific mechanisms that account for increased cardiovascular risk in T2DM remain unclear, as does whether the nature of atherosclerosis in T2DM is unique as compared to nondiabetes.

- Hyperglycemia exerts pathologic effects on vascular tissues by multiple complex pathways including oxidative stress, increased inflammation, lipotoxicity involving free fatty acids, glycation of proteins, and cellular insulin resistance to name a few; specific mediators involved in these responses have been identified and continue to be uncovered. There is a convergence of most if not all these mechanisms on increasing inflammation, promoting fibrosis and thrombosis, and accelerating atherosclerosis, with effects on endothelial cells, vascular smooth muscle cells, monocyte/macrophages, lymphocytes and platelets.

- Recent large clinical trials have not demonstrated clear benefits of tight glycemic control in preventing CVD outcomes. Long-term follow-up studies suggest that optimal glycemic control may confer a long-term CVD benefit in diabetes.

- Atherogenic dyslipidemia together with ectopic lipid accumulation in tissues, negatively affect glucose metabolism and insulin signaling in diabetes.

- Obesity, and in particular visceral adiposity, may increase inflammation and promote diabetes and CVD through endocrine and paracrine effects.

Diabetes mellitus and the burden of cardiovascular disease

The two- to fourfold increased risk of cardiovascular disease (CVD) in diabetes is unequivocal. Indeed, one could argue that the way in which we define diabetes — hyperglycemia — is only a marker for the major health threat in diabetes, which is CVD [1,2]. Cardiovascular (CV) events remain the major cause of death for those with diabetes, accounting for about 70% of all deaths [3]. Furthermore, the 7-year incidence of myocardial infarction (MI) in patients with type 2 diabetes (T2DM) and no history of MI may equal the incidence of patients with a prior MI but no diabetes [4]. Particularly concerning is the increasing prevalence of T2DM in younger patients, raising concerns about the future CV risk in such patients. Despite this, as discussed elsewhere, recent clinical trials fail to demonstrate the ability to decrease CV events by improving glucose control, a possible consequence of multiple issues. These complexities compel ongoing examination of the pathologic forces that promote diabetes and atherosclerosis in patients with diabetes, the focus of this chapter. Although the focus of attention in this area is inevitably coronary atherosclerosis and MI, it is important to note that diabetes increases the risk of atherosclerosis systemically, with increased peripheral arterial disease and cerebrovascular disease, worsens outcomes with CV interventions, and worsens outcomes with congestive heart failure. In considering the state of knowledge around the critical issues of the relationship between T2DM and CVD, key central challenges become evident. The first is the overlap between T2DM and CVD: both diseases are quite common — making causal separation difficult; can manifest themselves in distinct ways — suggesting oversimplification with our current diagnostic groups; have long preclinical phases — raising the prospect of earlier intervention; and appear to share some pathogenic mechanisms — again posing challenges in elucidating drivers of disease and therapeutic strategies. Such challenges can only be

met by further considering our current understanding of the disease processes themselves.

Insulin resistance (metabolic) syndrome

Patients with T2DM typically have an inadequate response to a given concentration of insulin as seen under controlled study conditions, so-called insulin resistance. It has been estimated that a third of the US population meet the criteria for the metabolic syndrome [5]. Early observations noted that insulin resistance, even before the presence of frank hyperglycemia, was often associated with other clinical conditions including central obesity, glucose intolerance, increased triglycerides, decreased levels of high-density lipoproteins, and hypertension. Importantly, all of these components of the metabolic syndrome also promote atherosclerosis. The constellation of these abnormalities was referred to as the metabolic syndrome (also called insulin resistance syndrome, syndrome X, Reaven's syndrome, among other names). Several lines of evidence specifically associated this clustering of cardiometabolic risk with visceral adiposity, as reflected by waist circumference. The clinical relevance of the metabolic syndrome was derived from data suggesting that the presence of the syndrome identified a significantly increased risk for future T2DM and CVD. Countering opinions suggested that the presence of metabolic syndrome offered no clinical utility, and that the future risk of CVD was no different than the sum of the individual metabolic syndrome components present in a given patient.

Despite these valid points, in addition to offering a convenient, appealing shorthand to clinicians who commonly encountered this risk cluster, discussions around the metabolic syndrome also provided a construct for studies into the nature and progression of atherosclerosis and cardiovascular complications in T2DM and those at increased risk for future diabetes. Subsequent attention has focused on clinical groups that overlap to various extents with the metabolic syndrome, including prediabetes (A1C $\geq$ 5.7%, <6.5%), impaired glucose tolerance, and impaired fasting glucose. These clinical designations may identify patients earlier in the natural history of T2DM and atherosclerosis, allowing potential inputs to diabetes and atherosclerosis to be isolated.

Insulin resistance and its associated abnormalities are all risk factors for the development of both diabetes and CVD. In response to insulin resistance, pancreatic β cells secrete increasing amounts of insulin, resulting in hyperinsulinemia. Whether or not hyperinsulinemia may contribute to atherosclerosis in patients with diabetes remains debated even as more evidence has argued against pharmacologic insulin as promoting atherosclerosis. The presence of hypertension in insulin resistance and T2DM is noteworthy, suggesting systemic changes in the vasculature and that mechanical forces found in hypertension, like shear stress, may already be priming the endothelium for pathogenesis. Several clinical observations are particularly intriguing in this regard. First, some relatively large studies find that when more sensitive screens for T2DM, like oral glucose tolerance testing, are done in nondiabetic patients, a significantly higher incidence of diabetes is uncovered among those with hypertension than among otherwise matched nonhypertensive subjects. Second, various studies using different means suggest that altered endothelial vasoreactivity may be among the first abnormalities in subjects destined for future T2DM. Preclinical studies support the notion that endothelial dysfunction, discussed elsewhere, may involve not just vasomotor function and hypertension but also glucose and fatty acid handling, key abnormalities in diabetes and atherosclerosis.

Insulin resistance syndromes are characterized by atherogenic dyslipidemia involving increased triglyceride levels (TG), low concentrations of high-density lipoprotein cholesterol (HDL-C), and smaller, denser low-density lipoprotein cholesterol (LDL-C). For a given LDL level, patients with smaller, denser LDL have increased levels of apolipoprotein B (apoB), which is more prone to oxidation and retention within the vessel wall. Oxidized LDL is considered a key element in foam cell formation and atherosclerosis. Hypertriglyceridemia in diabetes derives from increased secretion of TG-rich VLDL as well as impaired VLDL hydrolysis by enzymes like lipoprotein lipase (LPL). LPL has been reported to generate endogenous PPARα ligands, a potentially protective effect that may be lost in T2DM.

In attempting to identify the core defect in the insulin resistance syndrome, several approaches have implicated central obesity as a key culprit. Adipose tissue is now recognized as a dynamic, well-vascularized organ exerting endocrine, paracrine, and autocrine effects. Different depots of fat have distinct functional effects. Visceral adiposity is associated with increased inflammation and other abnormalities associated with diabetes and atherosclerosis [6]. Interestingly, some of the benefits seen with pioglitazone as a thiazolidinedione may involve expansion of subcutaneous fat, as a less dangerous depot, and contraction of visceral fat. Brown fat has been documented to be present in adult humans and may limit adiposity through thermogenesis. Especially relevant for this discussion are findings that report perivascular fat as brown-like in nature. Mechanisms linking adiposity to atherosclerosis in diabetes include increased free fatty acid (FFA) levels, increased cytokine release, and alterations in adipokines, for example adiponectin, as an anti-inflammatory protein produced more by subcutaneous than visceral fat, whose plasma levels correlate inversely with CV risk [7]. Recent studies implicate resident inflammatory cells in adipose tissue as promoting inflammation and diabetes. Clinical studies suggest that low-grade inflammation may predict future T2DM as well as CVD, further underscoring shared pathways of pathogenesis.

Insulin resistance syndromes are also thought to involve a more prothrombotic state. Shifts in the fibrinolytic balance have been reported, including increased plasminogen activator inhibitor 1 (PAI-1), which is made by both adipocytes and

endothelial cells, and decreased levels of the endogenous anticoagulant total plasminogen activator (tPA). Platelets also appear hyperreactive in insulin resistance and T2DM. Insulin resistance and T2DM can often have significant hepatic changes, influencing dyslipidemia and coagulation; increased deposition of hepatic fat may be part of this process.

Despite disappointing studies that failed to show decreased CV events through better control of glucose, one cannot ignore the extensive database identifying hyperglycemia as a pathogenic mechanism in either T2DM or insulin resistance. Increased glucose levels induce multiple cellular responses linked to inflammation and atherogenesis, as discussed further later. In fact, linear relationships between hyperglycemia and CV risk are evident even at levels of glucose and A1c that are considered within a normal range. Such relationships may be particularly relevant in prediabetes, impaired glucose tolerance/fasting glucose, and metabolic syndrome in which patients, and their vasculature, are exposed to hyperglycemia after meals, but can still achieve glucose levels after fasting or A1c values over time that are still in a "nondiabetic" range.

Putting this picture together, T2DM and the insulin resistance that typically accompanies it leads to a complex interplay of multiple clinical conditions that are generally unified in promoting inflammation and atherosclerosis. This pattern extends to earlier phases of diabetes, including prediabetes, impaired fasting glucose, and impaired glucose tolerance, as well as insulin resistance/metabolic syndrome. A central question regarding this focuses on early states associated with future risk of diabetes and cardiovascular disease. Definitions and criteria of the metabolic syndrome were revised several times by different medical associations, which reflect the disagreements and varied opinions regarding the etiology and nature of this syndrome. The criteria that make up the metabolic syndrome are listed in Table 70.1, with the syndrome considered present if any three of the five variables are found. Other groups have proposed other criteria that differ in various subtle if not semantic ways (Table 70.1). Certain aspects of the metabolic syndrome have also been defined differently for specific groups, like waist circumference as a surrogate for visceral adiposity among Southeast Asians, who may have more visceral fat at lower waist circumference.

Considerable controversy arose over the value of the metabolic syndrome and the rigor with which it had been established. Multiple prospective studies suggested that the presence of the metabolic syndrome was associated with an increased risk for future CVD [8]. However, conflicting opinions exist as to whether the presence of the syndrome confers a greater CVD risk than the risk associated with the individual components of the metabolic syndrome. Other criticisms include the medical value of diagnosing the metabolic syndrome if it will not lead to any alteration in management [9,10]. A further debate is whether the metabolic syndrome is a collection of unrelated risk factors, or combined by a common pathogenic mechanism. In 2010, the WHO Expert Consultation cast the metabolic

syndrome as an educational concept that focuses attention on complex multifactorial health problems, and recognized it as a premorbid condition rather than a clinical diagnosis, with limited practical utility as a diagnostic or management tool [11].

Although the pathogenesis of metabolic syndrome remains debated, insulin resistance—as formally defined in insulin clamp studies—has been proposed as a key link between the components of the metabolic syndrome, thus explaining the use of the term "insulin resistance syndrome" by some [12]. Given the constellation of abnormalities that seem to track together with insulin resistance, efforts have been made to identify the core defects, whether mechanistic or clinical, that account for the syndrome. Clinically, significant evidence would point to adiposity, and in particular visceral adiposity, as key driver on insulin resistance. Genetic predispositions may interact with environmental changes such as excessive caloric intake, decreased physical inactivity, and overall impaired energy balance that fosters increased storage of fatty acids to be stored in adipocytes as TG. This process may promote TG accumulation in ectopic locations, like visceral fat, liver and skeletal muscle [13,14]. This dysregulated energy balance is also associated with abnormalities in lipolysis, increased FFA, and increased specific molecular species like ceramides that have also been associated with insulin resistance and its complications [15]. The antilipolytic effects of insulin, which is a sensitive parameter of insulin action, may be impaired in insulin resistance states, leading to an increased rate of lipolysis and increased release of FFA in the circulation.

Another related core feature in insulin resistance appears to be inflammation, and in particular inflammation in visceral fat. Considerable interest has focused on accumulation of monocytes/macrophages in visceral fat where they may play a paracrine and endocrine role driving systemic inflammation and cardiometabolic complications. Consistent with this line of thinking are investigations testing the use of salicylates, as anti-inflammatory reagents, to treat diabetes [16].

Hyperglycemia, glycemic control, and CVD

Diabetes is associated with atherosclerotic CVD, with a greater extent of disease and more complicated consequences than in the nondiabetic population. Hyperglycemia defines the diagnosis of diabetes, and confers increased risk of vascular morbidity and mortality in a wide range of epidemiologic and cohort studies [17]. Meta-analyses have further shown that chronic hyperglycemia and elevated glycosylated hemoglobin are associated with an increased risk for CV events and all-cause mortality among patients with T2DM, likely independently from other conventional risk factors [18,19]. Interestingly, the risk relationship between hyperglycemia and measures like A1c may be present at levels well below the threshold considered diagnostic of T2DM. Nevertheless, despite this, three recent

Table 70.1 Criteria for clinical diagnosis of metabolic syndrome

	WHO (1998)	NCEP-ATP III (2001)	AACE (2003)	IDF (2005)	Joint statement IDF/NHLBI/AHA/ WHF/IAS/IASO (2009)
Definition	IGT, IFG, T2DM, or insulin resistance[a] + any 2 of additional criteria below:	Any 3 of 5 of the criteria below:	IGT or IFG plus any of the following based on clinical judgment	Central obesity + any 2 of the other criteria below:	Any 3 of 5 of the criteria below:

major clinical trials — Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease (ADVANCE), and the Veterans Affairs Diabetes Trial (VADT) — all failed to demonstrate clear benefits of aggressive glycemic control in decreasing CVD events [20–22]. That is in contrast to the clear benefit displayed in past trials demonstrating conclusively that microvascular complications can be reduced by better glycemic control in both patients with type 1 and type 2 diabetes [23–26]. Intense interest has focused on this "glucose paradox" in which hyperglycemia increases CV risk but lowering glucose fails to decrease CV events, at least to the extent that might have been predicted. Some antidiabetic agents may increase CV risk, offsetting any potential benefit in CV risk reduction. More aggressive glucose control, especially with agents like insulin, often brings hypoglycemia, which may increase CV events. This may be particularly an issue in older patients. The increased use of other interventions that decrease CV risk, as would be utilized to treat the control group in a

clinical trial, makes it increasingly harder to show benefit. Subtle variables like the duration of diabetes, and when treatments like statin use may have been implemented, may also be factors. Indeed, subgroup analyses do suggest that patients treated more aggressively for T2DM earlier in their natural history may experience better CV outcomes [27–29]. The results of several meta-analyses incorporating these recent studies demonstrated a benefit of improved glycemic control on nonfatal MI but no difference in overall mortality [30–32]. It should also be noted that longer follow-up may be necessary in order to see the benefit of diabetes therapies, as has been reported for significant CV risk reduction in T1DM in the DCCT/EDIC study and in T2DM patients in a UKPDS 10-year follow-up study [33,34]. Taken together, the case can be made that optimal glycemic control in patients with diabetes does confer a long-term CVD benefit even if management programs need to be tailored to individual patients and more information is needed along with better therapies [17,28].

Diabetes and atherosclerosis

Coronary artery disease in patients with diabetes is characterized by accelerated atherosclerosis occurring at an earlier age than the nondiabetic population. It is more extensive, diffuse in multiple arterial territories, and involves more distal and smaller coronary arteries. Angiography studies display fewer collateral vessels in diabetic patients compared with nondiabetics, which may result from failure of compensatory vasculogenesis in response to ischemia in diabetes [35]. Not infrequently these features limit and complicate revascularization possibilities. Plaque rupture and thrombus formation are more common in diabetes, leading to reduced outcomes after acute coronary syndromes, stroke, and heart failure.

Despite extensive examination of CVD in the context of diabetes, whether diabetic atherosclerosis differs fundamentally in terms of mechanisms from nondiabetic atherosclerosis or just an acceleration of the same processes remains poorly resolved. Atherosclerosis in diabetes is likely a multifactorial process [36]. Traditional coronary heart disease risk factors such as hypertension and dyslipidemia are prevalent in diabetes, influencing the risk of atherosclerosis by multiple mechanisms (Figure 70.1). Intravascular deposition of lipids and cellular debris characterize the atherosclerotic plaque formation. However, hyperglycemia, insulin resistance, and chronic inflammation are key processes promoting atherosclerosis development and progression in diabetes, by multiple mechanistic signaling pathways linked by common regulatory systems [37,38]. It is difficult to separate the effects of hyperglycemia from pro-atherogenic effects of other risk factors, especially dyslipidemia, in contributing to the accelerated atherosclerosis observed in diabetes.

In morphologic autopsy studies, atherosclerosis in diabetes is characterized by more extensive disease with distal involvement of coronary arteries as compared to nondiabetics, and increased plaque burden with higher rates of healed ruptured plaques observed. Larger necrotic cores along with inflammatory infiltrates of macrophages and T-cell lymphocytes have been reported in diabetic atherosclerotic vessels [39].

Intravascular ultrasound (IVUS) studies of atherosclerosis suggest that diabetes carries a greater baseline burden of coronary atherosclerosis with greater atheroma volume, smaller lumen dimensions, inadequate expansion of the vessel wall, and a more rapid progression [40]. Computed tomography (CT) imaging studies display higher coronary artery calcium scores in diabetes subjects without known coronary artery disease, than in nondiabetic individuals, with greater mortality rates. In addition, a higher rate of obstructive multivessel disease is seen in CT angiography of diabetic patients [41–43]. Overall, morphologic and imaging studies of diabetic atherosclerosis consistently demonstrate greater plaque burden, inflammation, and calcification than in nondiabetic individuals.

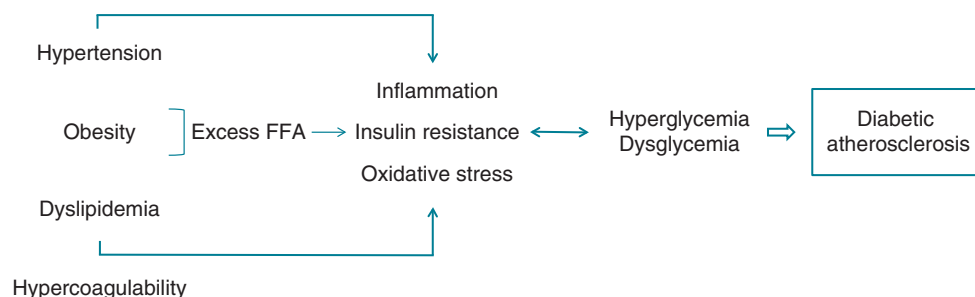
Similar to T2DM, T1DM is associated with early changes in vascular function, and an increased risk for premature coronary heart disease. Standard modifiable risk factors, such as smoking, lipids, and hypertension, enhance risk in T1DM, and renal disease with proteinuria, which can be found in T1DM, is independently predictive of coronary artery disease [44]. Multislice CT studies suggest that excess coronary artery calcification is seen more often in T1DM as compared to a relatively higher proportion of noncalcified plaques observed in patients with T2DM [45]. The fact that T1DM is less often associated with visceral adiposity suggests fundamental mechanistic inputs in the atherosclerosis that complicates T1DM and T2DM, even if final common pathways remain shared between these clinical entities. Atherosclerosis is initiated by the adhesion of monocytes to endothelial cells in the vascular wall, transmigrating into the subendothelium, and differentiating into macrophages [46]. Intravascular accumulation of lipids leads to LDL oxidation and induction of an inflammatory response. Macrophages, via uptake of lipids, transform into foam cells and accumulate in the vessel wall, resulting in fatty streak formation which constitutes the lipid core of the atherosclerotic plaque. During atherogenesis and atherosclerosis, inflammatory substances and growth factors are secreted by multiple sources, including endothelial cells, vascular smooth muscle cells (VSMCs), and inflammatory cells, stimulating infiltration of the intima by


Figure 70.1 Key components of diabetic atherosclerosis. An increase in CVD risk factors is common in diabetes, contributing to a greater atherosclerotic risk and macrovascular disease progression. Hyperglycemia, atherogenic dyslipidemia, and insulin resistance are connected by complex pathophysiologic interactions to the initiation and progression of atherosclerosis in diabetes. The inflammatory response in the vasculature and metabolic tissues has arisen as an appealing unifying mechanism that may mediate cellular and systemic responses that increase atherosclerosis, insulin/resistance/diabetes, and their intersection. FFA, free fatty acids.

leukocytes and the migration and proliferation of VSMCs, which appear responsible for the formation of a collagen-rich fibrous cap [47]. Cell death and newly recognized processes such as autophagy contribute to the highly thrombotic necrotic core found in lesions. Ongoing accumulation of macrophages, lymphocytes, lipids, and connective tissue matrix, surrounded by a fibrous cap, represents the mature atherosclerotic plaque. Activated metalloproteinase enzymes further degenerate the collagen matrix, and the proliferation of vasa vasorum into the adventitia may lead to intraplaque hemorrhage, further promoting plaque necrosis and thinning of the fibrous cap. Given that the fibrous cap is what separates the circulation, with its highly active, efficient coagulation system, from the thrombogenic necrotic core, the stability of the fibrous cap becomes a critical factor that determines whether or not plaque rupture and myocardial infarction will occur. Features of instability and vulnerability of the plaque include a large lipid/necrotic core, a thin fibrous cap, plaque hemorrhage, and an inflammatory infiltrate rich in monocytes and macrophages in the shoulder region. New insight into monocyte biology and monocyte transition to macrophages has also revealed the existence of different monocyte subtypes, including ones that limit inflammation and atherosclerosis, and others that promote these processes. Hyperglycemia, FFA, and diabetes may shift macrophage subtypes towards those that are more pathogenic.

Insulin resistance and diabetes may further stimulate and induce many of the higher pathogenic aspects of atherosclerosis. Insulin resistance in macrophages enhances apoptosis and promotes formation of necrotic core in advanced atherosclerotic plaques [48]. Increased wall stress, as seen with hypertension, and the characteristics of blood-flow, as seen with increased shear stress, contributes to the heightened thrombogenicity of the vessel wall. In diabetes, a reduction in the strength of the fibrous cap has been reported, which may raise the likelihood of plaque rupture. Diabetes is also associated with a hypercoagulable state, with increased PAI-1 levels and decreased tPA, changes associated with increased propensity of clot formation. Platelets in diabetes also appear hyperfunctional [49].

Pathogenesis linking metabolic syndrome, diabetes, and atherogenesis

Multiple mechanisms likely foster atherosclerosis in diabetes. Hyperglycemia and insulin resistance mediate vasoconstrictive, proinflammatory, and prothrombotic vascular responses which promote pro-atherosclerotic events [17]. Atherosclerosis in diabetes is accelerated by endothelial and VSMC dysfunction, immune and inflammatory activation, which are driven by metabolic derangements including hyperglycemia, impaired insulin signaling, and dyslipidemia with elevated FFA production. Various inputs to these responses will be considered here.

Hyperglycemia and glucotoxicity

The mechanisms through which hyperglycemia promotes the development of vascular disease remain incompletely understood. Hyperglycemia may promote atherosclerosis and CVD by altering hepatic and peripheral lipoprotein metabolism, resulting in changes such as increased triglycerides, lower HDL, and smaller, denser LDL that may be more prone to uptake in the vessel wall and oxidation. Hyperglycemia also facilitates the development of proteinuria and chronic kidney disease in patients with T2DM. The vascular wall, and in particular the microvasculature, is sensitive to changes in glucose concentration. Hyperglycemia exerts adverse effects on endothelial function, inhibiting the availability and activity of nitric oxide (NO), and impairing endothelium-dependent vasodilatation in diabetes subjects [50]. Evidence from multiple experiments supports the view that hyperglycemia induces a range of pro-atherogenic effects, through several suggested mechanisms (Figure 70.2). The strength of such data only adds to the confusion over why treating hyperglycemia has not had more definitive effects on decreasing CV events.

Oxidative stress and ROS

Hyperglycemia enhances oxidative stress by inducing reactive oxidative species (ROS), promoting vascular dysfunction. Oxidative stress has a central role in the development of atherosclerosis through activation of several pathways involved in the pathogenesis of diabetic complications [51]. Through these pathways, oxidative stress promotes inactivation and reduced bioavailability of NO, increase in VSMC proliferation, macrophage adhesion, vascular apoptosis and remodeling, and enhances platelet activation. Oxidative stress can also lead to increased production of oxidized LDL in the vessel wall. Hyperglycemia induces overproduction of superoxide and NADPH oxidase, both a source of vascular oxidative stress in diabetes, which can damage vascular cells by activating and interacting with different pathogenic mechanisms as outlined.

DAG production and PKC activation

Hyperglycemia and changes in fatty acid oxidation increase the production of diacylglycerol (DAG) from glucose, thus increasing activation of the intracellular signaling molecule protein-kinase C (PKC). Activation of PKC isoforms phosphorylates various target proteins and affects vascular permeability, decreases NO production, and promotes extracellular matrix synthesis, cell growth, leukocyte adhesion, and cytokine activation [52]. PKC increases oxidative stress through activation of NADPH oxidase, decreasing NO production [53]. PKCs further impair insulin actions in the vasculature.

Polyol and hexosamine pathways

During hyperglycemia, endothelial cells are unable to reduce glucose uptake, resulting in glucose metabolism that is shifted to other pathways. Increased activity of aldose reductase and the polyol pathway due to high influx of glucose, results in

toxic accumulation of compounds such as sorbitol which generates ROS and promotes vasoconstriction [54]. Excess fatty acid oxidation may also stimulate diabetic complications by increasing the flux of fructose 6-phosphate into the hexosamine pathway [49–51]. The hexosamine pathway causes reversible modifications at regulatory phosphorylation sites on proteins involved in insulin signaling. Hexosamines may also mediate hyperglycemia-induced increase in gene transcription and activation of transforming growth factors (TGF) and PAI-1, as well as inhibit endothelial NO synthase (eNOS) activity in endothelial cells.

Increased intracellular AGE formation

Glucose-induced formation of nonenzymatic advanced glycation end products (AGE) have major importance in the pathogenesis of vascular dysfunction in diabetes. AGEs are formed through prolonged exposure of proteins and lipids to high concentrations of circulating glucose. Many different heterogeneous proteins, lipids and nucleic acids undergo irreversible post-translational modifications through glycation, with cross-linking of the proteins with reducing sugars. Indeed, the use of the A1c as a long-term measure of glucose control is simply a measure of the glycation of hemoglobin. Amino

groups on proteins are bounded to glucose moieties due to hyperglycemia, and undergo nonenzymatic glycosylation, reduction, and Amadori rearrangements, eventually leading to the formation of AGE. AGE is implicated in the atherosclerotic process, either through their direct effects or by AGE interaction with the receptor for AGE (RAGE). High glucose levels and oxidative stress increase AGE–RAGE interactions, altering cellular signaling, promoting gene expression and enhancing leukocyte recruitment and the release of pro-inflammatory and adhesion molecules [55]. AGE generates ROS by stimulating NADPH oxidase activity, reducing eNOS activity and endothelial production of prostacyclin [56]. Levels of AGE in the serum of T2DM patients are negatively associated with endothelial vasodilatation, and AGE is associated with increased vascular stiffness. AGE and its receptor-ligands interactions activate NF-κB, a key proximal mediator of inflammatory responses, further increasing vasoconstrictive and proinflammatory responses. Accordingly, diabetic mouse models show that RAGE activation by pro-inflammatory protein ligands has a central role in the formation and progression of atherosclerotic lesions [57]. AGE–RAGE interactions also induce pro-coagulant forces in endothelial cells, increase expression of tissue factor by monocytes, activate inflammatory response,

stimulate pro-thrombotic pathways and an increase in matrix degrading enzymes associated with plaque rupture.

NF-κB activation

High glucose concentrations enhance the activation of NF-κB, which is a key pro-inflammatory nuclear transcription factor that controls multiple inflammatory targets. NF-κB activation by hyperglycemia increases expression of endothelial adhesion molecules, facilitating monocyte adhesion and vessel wall entry. Investigators have shown that transient hyperglycemia can induce epigenetic changes in a promoter region of NF-κB subunit in aortic endothelial cells, suggesting that transient hyperglycemia may cause persistent atherogenic effects during subsequent normoglycemia [58]. Hyperglycemia-induced activation of PKC has also been implicated in the activation of NF-κB in endothelial cells and VSMCs [59,60]. Studies have established links between activation of NF-κB, development of inflammatory phenotype, insulin resistance, and endothelial dysfunction. NF-κB inhibition may be a therapeutic target for treating diabetes and CV disease.

Overall, from a mechanistic perspective, hyperglycemia may induce chronic vascular complications via formation of toxic metabolites such as AGE, ROS, sorbitol, and persistent activation of PKC pathways, promoting an inflammatory milieu and accelerating atherosclerosis (Figure 70.2) [59–61]. Nonetheless, it is difficult to differentiate the relative contribution to the progression of atherosclerosis in diabetes from hyperglycemia itself versus other effects of dyslipidemia and other CVD risk factors often found in association with hyperglycemia and diabetes.

Insulin resistance and hyperinsulinemia

Insulin resistance has been associated with increased risk of coronary artery disease, and may promote atherosclerosis as an independent risk factor [8,62,63]. Insulin resistance can derive from defective insulin receptor signaling or overstimulation of insulin receptor pathways caused by hyperinsulinemia. The formal definition of insulin resistance involves demonstration of the need for higher infusion rates of insulin in order to maintain glucose at a certain level, thus establishing a cellular level of "resistance" to insulin. After binding to its cognate cell surface receptors, insulin activates the insulin receptor tyrosine kinase that phosphorylates insulin receptor substrates (IRS), resulting in stimulation of two divergent pathways (Figure 70.3): phosphatidylinositol-3 kinase (PI-3K)-dependent pathway, which mediates metabolic and anti-apoptotic effects, and the mitogen-activated protein kinase (MAP-K) which is linked to proliferative and mitogenic effects promoting cell growth and proliferation. In insulin-resistant T2DM and in obese patients, the PI-3K pathway, but not MAP-K, is resistant to insulin stimulation, resulting in a preferential activation of the MAP-K pathway [64]. MAP-K signaling in insulin-resistant patients is thought to have atherogenic and mitogenic properties that lead to atherosclerosis, while the anti-inflammatory, anti-atherogenic effects of physiologic levels of insulin, which

depend on the PI-3K pathway, are lost. Compensatory hyperinsulinemia increases the production of endothelin and vascular adhesion molecules through a MAP-K dependent pathway. Consequently, cellular growth and migration is stimulated, together with production of prothrombotic and profibrotic factors, promoting atherosclerosis [65]. Furthermore, NO production is mediated via the PI-3K signal transduction pathway and is therefore impaired in insulin resistance states, promoting endothelial dysfunction and accelerated atherosclerosis.

Insulin resistance can promote atherosclerosis both by altering systemic processes like dyslipidemia and hypertension, as well as through impaired insulin signaling at the level of the cells of the vessel wall, including endothelial cells, VSMCs, and macrophages. These cells have insulin receptor-mediated signaling pathways that are repressed during hyperinsulinemia [66]. In endothelial cells, downregulation of insulin receptor levels through altered IRS/PI-3K pathways, results in reduced levels of eNOS activation and NO production, and increases in expression of the leukocyte adhesion molecule VCAM-1 involved in leukocyte entry into the vessel wall. Insulin can also activate the MAP-K dependent pathway which regulates secretion of the vasoconstrictor endothelin-1 (ET-1) from the endothelium. In VSMCs, insulin resistance may promote proliferation and migration of VSMCs into the subintimal space while also inducing VSMC apoptosis. The loss of VSMCs, an important cellular source of collagen and other matrix materials essential to fibrous cap formation, can lead to fibrous cap thinning and plaque necrosis. In monocyte-derived macrophages, insulin receptors are downregulated during obesity and hyperinsulinemia, and the impairment in insulin signaling promotes macrophage apoptosis in atherosclerotic lesions [67]. Elevated levels of saturated fatty acids, characteristic of insulin resistance state, can also amplify the apoptotic response in macrophages.

Relating preclinical studies of insulin signaling and its relationship to inflammation and atherosclerosis, to clinical issues regarding diabetes, can be challenging on several fronts. One of these involves the differences between acute insulin exposure, as can happen experimentally, and chronic hyperinsulinemia, which is encountered clinically in patients with insulin resistance. Insulin has been shown to have acute anti-inflammatory and vasodilatory effects. Chronic insulin stimulation, and other changes associated with chronic hyperinsulinemia, including insulin receptor changes, may have different effects than those seen in experimental models. The effects of endogenous insulin release and exogenous insulin administration may also have different effects. In the ORIGIN trial, subjects with recently diagnosed diabetes did not have any significant lowering of CV events with insulin therapy; at the same time, exogenous insulin had no adverse effects on promoting CV issues [68].

Dyslipidemia, lipotoxicity, and lipid mediators of insulin resistance

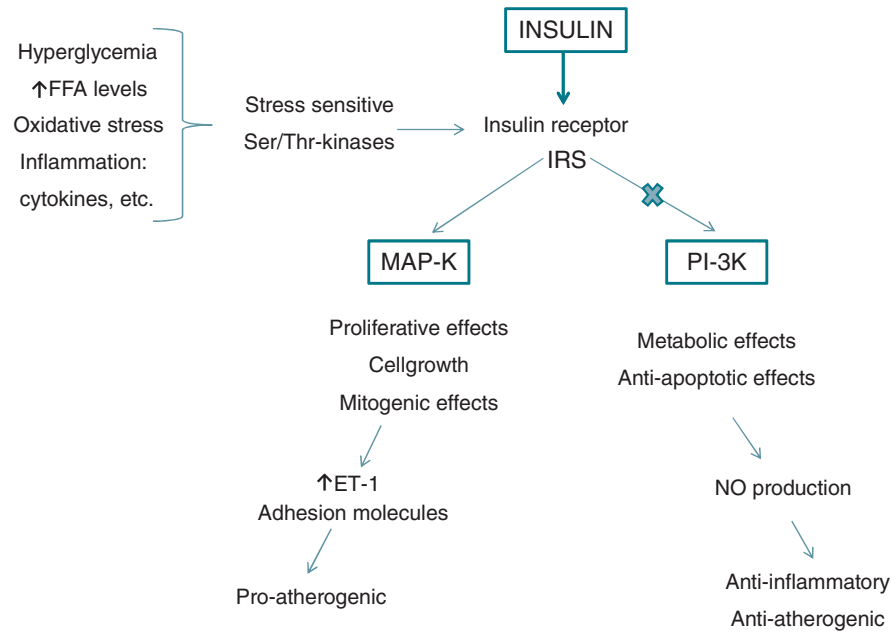
Dyslipidemia is a common finding in people with T2DM, who typically have increased plasma concentrations of TG and


Figure 70.3 Classic insulin/insulin receptor cellular signaling pathways. PI-3K signaling pathway impairment, characterizing insulin resistance, leading to vascular dysfunction and pro-atherogenic effects. MAP kinase pathways are also modulated by insulin signaling with differential effects on cellular responses. IRS, insulin receptor substrate; PI-3K, phosphatidylinositol 3-kinase; MAP-K, mitogen-activated protein kinase; ET-1, endothelin-1; NO, nitric oxide; FFA, free fatty acids.

low plasma levels of HDL-C. Diabetic patients have usually only mild elevation in plasma concentrations of LDL-C, but may have more atherogenic small, dense LDL. T2DM patients generally have more LDL particles than people without diabetes, and the increased LDL particles number may contribute to atherogenesis and CVD risk by increased entry into the arterial wall and an increased propensity for oxidation [69,70]. Meta-analyses clearly show that the reduction of LDL-C concentrations results in an important decrease in major coronary events in diabetic patients, at least if not more, than nondiabetic individuals [71,72]. Decreased HDL-C levels and a change in HDL composition, together with a decrease in the concentration of apolipoprotein A1, are observed in humans with T2DM. These changes impair the removal of excess cholesterol from macrophages and foam cells by HDL, which may be important in the early phase of the atherosclerotic plaque.

Lipotoxicity is a general term that refers to the deleterious effects of increased adiposity on metabolic responses [73]. Lipotoxicity is also used to refer to the effects of elevated FFA levels on the vasculature and other organs. Ectopic lipid accumulation, as is found in the visceral fat depot, skeletal muscle, and the liver, creates an imbalance between lipid uptake and oxidation, which is implicated in the pathogenesis of insulin resistance. Impaired ability of adipocytes to store additional TG, contributes to increased accumulation of lipids and their metabolites in other tissues. Excess of circulating FFA inhibits glucose transport and phosphorylation, with subsequent reduction of glucose oxidation and muscle glycogen

synthesis, inducing insulin resistance in skeletal muscle [74]. The increase in liver fat also impairs the ability of insulin to regulate gluconeogenesis. Excess accumulation of lipids in the heart may promote cardiac lipotoxicity and development of myocardial dysfunction. Underlying molecular mechanisms invoked include increased lipid uptake or impaired mitochondrial oxidative function leading to accumulation of TGs and other toxic lipid compounds discussed later, which may cause myocyte loss through apoptosis and induction of prohypertrophic signaling [75].

Several toxic lipid metabolites including ceramide, DAG, and long-chain acyl-CoA are associated with lipotoxicity and contribute to the activation of PKC dependent signaling pathways and insulin resistance [76]. Accumulation of ceramides is associated with impaired PI-3K/Akt2 activation, subsequent increased expression of gluconeogenesis enzymes, and decreased insulin-mediated glycogen synthesis. Lipid excess with DAG activation of PKCs impairs insulin signaling and insulin receptor activation, contributing to insulin resistance in the muscle and liver [15]. Other kinases such as IκB kinase (IKK) complex and the c-Jun NH2-terminal kinase (JNK) are also activated by raised plasma FFA levels. FFA can reduce NO production through PKC-dependent stimulation of NADPH oxidase, increasing also the production of ROS [77]. Elevated FFA increases markers of endothelial activation such as ICAM-1, VCAM-1, and myeloperoxidase, and may facilitate endothelial damage by augmenting apoptosis. Consistent with this, hypertriglyceridemia is also associated with impaired vascular

reactivity. TG-rich lipoproteins enhance a pro-inflammatory phenotype in endothelial cells and increase TNFα expression and the adherence of monocytes and macrophages to endothelial cells [78]. Endogenous, physiologic hydrolysis of TG-rich lipoproteins generates endogenous PPARα ligands that may limit inflammation and atherosclerosis [79].

Evidence from human studies suggests that increasing FFA levels by lipid infusion can inhibit insulin signaling and insulin-stimulated glucose disposal [80]. One challenge with many such studies is their reliance on heparin infusion, which displaces lipoprotein lipase (LPL) from the endothelial surface, allowing it to hydrolyze circulating TG-rich lipoproteins. Such methods do generate high levels of FFA but fundamentally disrupt the physiologic role of LPL on the endothelial surface. In addition, FFA-induced impairment of endothelial function, has been reported as being reversed by an inhibitor of the renin-angiotensin system (RAS) and also by a PPAR gamma agonist [81,82].

Metabolic inflammation and adiposity

Obesity is associated with hypertension, dyslipidemia, and diabetes, all of which accelerate atherosclerosis. Increased adiposity alters lipoprotein metabolism, increases inflammation, and stimulates changes in adipocyte-generated cytokines, also known as adipokines (discussed further later), which help link obesity and CVD complications [83].

Increased circulating levels of inflammatory markers have been noted in obese individuals and in patients with the metabolic syndrome. Among nondiabetic subjects, elevated C-reactive protein (CRP) levels were related to measures of insulin resistance; the presence of inflammatory mediators may predict future occurrence of T2DM [84–86]. Furthermore, studies display a significant association between increased inflammatory markers, CV risk indicators, and CV events in T2DM [87–89]. Visceral fat accumulation is a predictor of CV events, suggesting that inflammation induced by adipose tissue may be a factor in the development of atherosclerosis and complications of the metabolic syndrome [90]. Obesity is characterized by low-grade chronic inflammation, which acts as a regulatory process that links multiple risk factors for atherosclerosis and its complications [91]. Inflammatory stimuli in obesity regulate secretion and activation of chemokines, adhesion molecule expression, and release of vasoactive mediators. Metabolic abnormalities such as dyslipidemia, hyperglycemia and insulin resistance augment the inflammatory response by multiple cellular pathways, as described earlier. The release of cytokines form a chronic low-grade inflammatory state (referred to by some as "metaflammation") generated by various cell types in response to an excessive energetic nutrient load which may be a key mechanism causing metabolic dysfunction and insulin resistance [92].

Mechanisms of metabolic inflammation

Inflammatory cytokines, such as TNFα, interleukins IL-6, IL-1β, CCL2 and others, are increased in adipose depots. In response to excess nutrients, cytokine activation in the setting of obesity is enhanced not only in the adipose tissue, but also in tissues like the liver, muscle and pancreas, which are also exposed to the inflammatory state induced in obesity. Adipose tissues display increased activation of intracellular kinases such as c-Jun N-terminal kinase (JNK), inhibitor of κ kinase (IKK) and protein kinase R (PKR), as well as the toll-like receptors (TLRs) of the immune system, stimulating downstream signaling pathways and inflammation. These inflammatory mediators may also contribute directly to insulin resistance as discussed. Activation of kinases results in serine phosphorylation of insulin receptor substrate 1 (IRS-1), inhibiting the insulin receptor signaling cascade [92]. Furthermore, these kinases can promote inflammation by activating transcription factors such as NFκB, which then increases expression of other inflammatory mediators.

Recent studies have drawn attention to the infiltration of inflammatory cells, including macrophages and T cells in visceral fat [93]. Cytokines in this setting can stimulate macrophage maturation in a "classical" (type M1) profile which is pro-inflammatory, in contrast to an "alternative" (type M2) phenotype which has anti-inflammatory effects, as noted earlier. Changes in the proportion of different T-cell types during obesity promote the phenotypic transition that occurs from M2 cells secreting anti-inflammatory molecules towards M1 macrophages releasing pro-inflammatory cytokines such as TNFα, IL-6, and IL-12 [94]. This line of investigation provides direct connects between inflammation, and inflammatory cells like macrophages, and the insulin resistance found during obesity and in T2DM.

Endoplasmic reticulum (ER) stress is also a novel pathway increasingly implicated in promoting inflammation in obesity and insulin resistance. The ER is the major site in the cell for protein folding and trafficking. Failure of the ER's normal adaptive capacity results in activation of the unfolded protein response (UPR), which intersects with many different inflammatory and stress signaling pathways [95]. ER stress may be further induced by hyperglycemia, increased fatty acids and hypoxia, and may initiate apoptotic pathways and production of oxidative stress, promoting inflammation and metabolic disease.

Gut microbia influence metabolism in the obese state through bacteria and host interactions. Changes in the gut microbia can affect insulin sensitivity and metabolic inflammatory state in adipose tissue and in peripheral organs [96].

Adipokines

Adipocytes secrete bioactive proteins called adipokines, which include various cytokines, chemokines, and hormones. These adipocyte mediators have been implicated in inflammation, especially in obesity in which adipose tissue is infiltrated by pro-inflammatory macrophages. Some of these adipokines are pro-inflammatory such as leptin, TNFα, and IL-6, while others have anti-inflammatory and protective effects against the formation of atherosclerotic lesions, such as adiponectin which is markedly reduced during obesity.

Adiponectin, which is produced more by subcutaneous fat than visceral fat, reportedly limits inflammation and atherosclerotic responses; adiponectin levels in humans are lower in obesity, insulin resistance, diabetes, and CVD [97]. Serum high-molecular-weight adiponectin levels are significantly lower in men with coronary artery disease, and adiponectin levels were shown to be inversely correlated to the progression of coronary artery calcium [98,99]. Adiponectin receptors activate the AMP kinase (AMPK) pathway and the peroxisome proliferator-activated receptor alpha (PPARα) pathway in the liver, increasing insulin sensitivity and decrease inflammation. Adiponectin reportedly suppress VSMCs proliferation and transformation of macrophages to foam cells, with reduction of lipid accumulation in foam cells. Adiponectin may prevent proliferation and transmigration of fibroblasts in the vascular adventitia. Expression of adiponectin is under the control of PPARγ.

Leptin is a central nervous system hormone involved in appetite regulation. Plasma leptin levels are increased in obesity. Leptin may also produce pro-inflammatory effects, enhancing cellular immune responses, proliferation of macrophages, activation of cytokines, and increases in ROS production. Leptin may also have procoagulant effects. Taking these factors together, leptin may be involved in modulating atherogenesis. A study in T2DM demonstrated that increased leptin levels are associated with coronary atherosclerosis, independent of insulin resistance [100]. Not unlike insulin, leptin resistance has also been suggested as a clinical syndrome. Another important adipokine is resistin, which is expressed in macrophages of atherosclerotic lesions. Resistin induces the expression of adhesion molecules, promoting the adhesion of monocytes to the vascular wall. It is associated with insulin resistance and coronary artery disease [101,102].

Additional obesity-induced inflammatory mediators in adipose tissue include TNFα, which stimulates lipolysis and inflammation and is associated with insulin resistance. Circulating IL-6 is increased in obese people, regulating immune response and inflammation, and contributing to insulin resistance in the liver and muscle. Proteins that recruit inflammatory cells to specific sites are known as chemoattractant cytokines, or more simply chemokines. Monocyte chemoattractant protein-1 (MCP-1), an important chemokine released by endothelial cells and adipocytes, helps recruit monocytes and other cells expressing the MCP-1 receptor to adipose tissue and elsewhere. Adipocytes also produce the procoagulant and CV risk factor PAI-1, thus connecting adiposity to hypercoagulability [103]. Levels of angiotensinogen, a central player in the renin-angiotensin system, also correlates with accumulation of adipose tissue, and has been reported to stimulate lipogenesis and vascular inflammation, connecting these responses to hypertension.

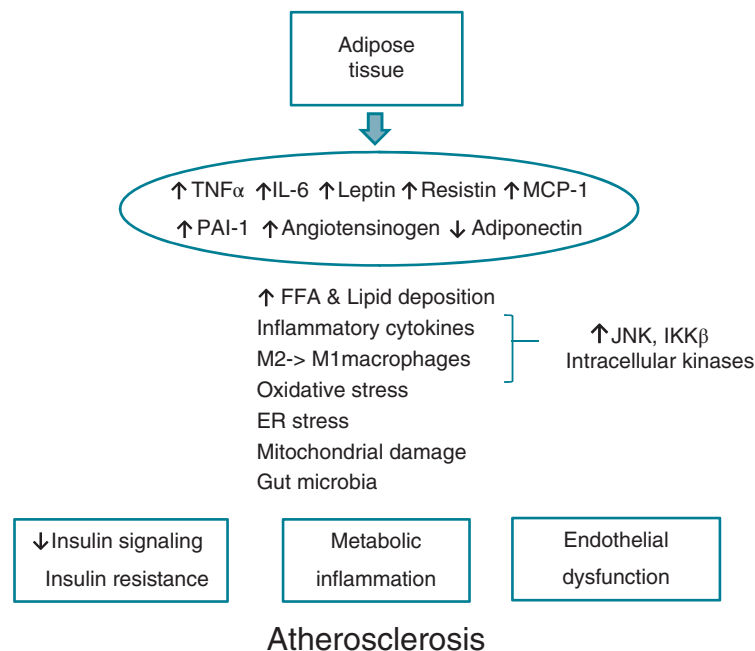
Increased visceral fat results in dysregulation of the different adipokines, contributing to the development of metabolic syndrome, and to the generation of pro-inflammatory, pro-thrombotic, and ultimately pro-atherosclerotic components. Adipose tissue distribution is important for atherosclerotic


Figure 70.4 Adiposity and vascular responses. Excess adiposity exerts multiple cellular effects that can promote inflammation and atherosclerosis. Obesity, especially increased visceral adiposity and other sites of increased lipid storage in abnormal locations (liver, muscle), is associated with excess FFA and specific lipid metabolites, alteration in hormones and inflammatory mediators like cytokines. Together these factors are thought to increase insulin resistance and promote inflammation via multiple signaling pathways and inflammatory mediators. TNFα, tumor necrosis factor alpha; IL-6, interleukin 6; PAI-1, plasminogen activator inhibitor 1; MCP-1, monocyte chemoattractant protein-1; FFA, free fatty acids; JNK, Jun N-terminal kinase; IKKβ; inhibitor of k kinase beta.

risk. Visceral, truncal fat is associated with more vascular and metabolic risk than peripheral fat, possibly due to the pattern of adipokines and cytokine release from visceral fat, and its access to the portal circulation [83].

Overall, metabolic inflammation is characterized by a low-grade chronic inflammation, induced during obesity in response to excess nutrients, by release of inflammatory cytokines, adipokines, and macrophages [92]. Impaired signaling pathways and triggers such as ER stress, hypoxia, ROS generation, and altered gut microbia, further maintain the chronic inflammatory state, contributing to insulin resistance and metabolic dysfunction (Figure 70.4).

Conclusion

The incidence of obesity and diabetes is rising worldwide and will impact increasingly on the nature and care of CVD. Diabetes elevates the risk for CVD complications, particularly atherosclerotic vascular disease. The cluster of abnormalities typically associated with diabetes and often prediabetes known as the metabolic syndrome or insulin resistance syndrome incorporates various CVD risk factors, and predicts future diabetes and coronary artery disease. Inflammation, including adipose inflammation, and excess adiposity, are emerging as a key mechanism for the metabolic derangement found in T2DM, with considerable overlap with the changes seen in the arterial wall with diabetic atherosclerosis. Hyperglycemia, insulin resistance and lipoprotein abnormalities, are all connected through complex pathophysiologic interactions, further promoting accelerated atherosclerosis and CVD in diabetes. New insight has been generated into molecular mechanisms involved in these processes. These mediators provide new opportunities for better predictive biomarkers and therapeutic targets.

Endothelial function and metabolic syndrome

Xinpu Chen and Sridevi Devaraj

Texas Children's Hospital, Baylor College of Medicine and Texas Children's Microbiome Center, Houston, TX, USA

Key points

- Metabolic syndrome is highly prevalent and predisposes to increased risk of diabetes and cardiovascular disease.
- Metabolic syndrome is a pro-inflammatory state.
- Endothelial dysfunction is a key early event in atherogenesis and is pronounced in patients with metabolic syndrome.
- The measurement of endothelial function *in vivo* is far from optimum and newer biomarkers are needed.
- Two biomarkers of endothelial function that hold promise are the evaluation of endothelial microparticles and endothelial progenitor cells.

Introduction: the metabolic syndrome

The metabolic syndrome (MetS) comprises a cluster of cardiometabolic risk factors, with insulin resistance (IR) and central adiposity being the main features. The National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III) defined the MetS as the presence of any three features of the five outlined (central obesity, dyslipidemia (i.e., high triglycerides, low HDL), hypertension, and impaired fasting glucose) [1–3]. Approximately 35% of US adults have the MetS and this is a global health issue. Also, the prevalence of MetS increases with age and is more in certain ethnic groups. MetS confers a two- to fourfold increased risk for cardiovascular disease (CVD) and fivefold increased risk of diabetes [1–3]. Several lines of evidence have reported that MetS is a proinflammatory state.

Endothelial dysfunction and MetS

The endothelium plays an important role in maintaining vascular health and integrity and secretes endothelium-derived relaxing and endothelium-derived contracting factors, such as nitric oxide, which plays a pivotal role in the maintenance of vascular tone and reactivity. Diminished production or availability of nitric oxide and/or imbalance in the ratio of endothelium-derived relaxing and contracting factors results in endothelial dysfunction. Endothelial dysfunction is commonly associated with the development and progression of a wide range of cardiovascular diseases. A key early event in atherosclerosis is endothelial cell dysfunction, which is precipitated by several noxious insults including obesity, hypertension, dyslipidemia, hyperglycemia (all features of MetS), as well as other insults including smoking [4–6]. Many investigators have reported endothelial dysfunction in patients with MetS. One of the most widely used measurements of endothelial function is flow-mediated dilatation (FMD), which is a nitric oxide-dependent, endothelium-dependent vasodilatation [7]. In one of the first reports on endothelial dysfunction and its association with MetS, Esposito et al. [8] showed that compared with 60 control subjects matched for age and sex, patients with the metabolic syndrome had decreased endothelial function. In the Framingham Offspring participants, Hamburg et al. [9] demonstrated that MetS was associated with decreased FMD. Furthermore, as the number of MetS components increased, there was worsening of endothelial dysfunction. Lteif et al. [10], using leg blood flow measurements, showed that patients with MetS had worse endothelial function. Also, in the Prospective Study of the Vasculature in Uppsala Seniors (PIVUS) study [11], using different techniques to assess vasodilatation in conduit and resistance arteries in MetS, the authors showed decreased FMD in patients with MetS. In the Northern Manhatten study (NOMA), Suzuki et al. [12] reported that MetS was associated with decreased FMD and increased cardiovascular disease over an 81-month follow-up period. All of the above reports clearly document that MetS patients have impaired endothelial function. Since endothelial vasodilator function is important in maintaining vascular integrity, the loss of endothelial

---

function would be expected to result in increased cardiovascular burden. This has major implications with regards to subsequent CVD.

Endothelial microparticles (EMP)

Inflammation also begets increased oxidative stress and apoptosis which results in cellular release of microparticles (MP). MPs are small membrane fragments that are shed from various cell types and range between 0.1 and 1.0 μm [13–17]. The release of MPs is regulated by different stimuli such as shear stress, physiologic agonists, proapoptotic stimulation, and damage. MPs are membrane vesicles with procoagulant and proinflammatory properties. MPs are present in blood from healthy individuals and elevated in patients under pathologic states, such as sepsis, various clinical situations associated with thrombosis, and in diabetic patients, strengthening the notion that MPs may play a role in these diseases [13–16]. Indeed, MPs can be considered as vectors of biologic messages, such as induction of endothelial and vascular dysfunctions.

The endothelium is one of the primary targets of circulating MPs. Under normal conditions, MPs contribute to the regulation of endothelial cell functions, including coagulation and inflammation. MPs derived from endothelium are referred to as endothelial microparticles and appear to contribute to a procoagulant and proinflammatory phenotype that leads to endothelial dysfunction [18].

Endothelial microparticles and MetS

In MetS, few groups have studied EMPs [19,20]. Tissue factor-positive MPs are associated with components of the MetS in patients with well-regulated type 2 diabetes. Recently, Arteaga et al. [19] reported endothelial cell MP release, and increased binding of MPs from endothelial cells and platelets to leukocytes in patients with the MetS. Chironi et al. [20]showed in patients with MetS, that the leukocyte-derived MP level is higher than in those free of such syndrome and increased gradually in parallel with the number of components of MetS.

In a large study of 88 subjects with MetS, Helal et al. [21] showed significantly increased EMPs in these patients compared to matched controls and they correlated significantly with the features of MetS, namely, waist circumference, blood pressure, and dyslipidemia.

In conclusion, data from these studies demonstrates that elevation of circulating EMPs is associated with the cluster of abnormalities characteristic of the MetS, and could be an early predictor of metabolic risk. Although MP are known to play a pathogenic role in more advanced stages of atherosclerosis, they could also play a detrimental role in conditions such as the MetS. Further studies are required to determine the validity of using MP as biomarkers for progressive metabolic abnormalities in MetS.

Endothelial progenitor cells (EPC)

In recent years, there has been much interest in a subtype of progenitor cells, isolated from bone marrow, umbilical vessels, and peripheral blood of adults which have the capacity to circulate, proliferate, and differentiate into mature endothelial cells, termed endothelial progenitor cells (EPCs) [22–25]. EPCs circulate in the blood and appear to home preferentially to sites of vascular or tissue injury, contributing significantly to both re-endothelialization and neoangiogenesis. There are, however, many controversies with regard to the exact definition and characterization of human EPCs. The most often used characterization of EPCs is the assessment of surface markers such as CD34 and vascular endothelial growth factor receptor-2, VEGFR-2 (KDR). Indeed, the assessment of $CD34^+KDR^+$ combination is the only EPC phenotype that has been demonstrated repeatedly and convincingly to be an independent predictor of cardiovascular outcomes.

EPC and cardiovascular events

Decreased EPC number and functionality is associated with increased cardiovascular events [26–30]. In a 10-month follow-up study, Schmidt-Lucke et al. [26] showed that the level of $CD34^+KDR^+$ cells independently predicted cardiovascular events and progression of atherosclerosis in a mixed population of healthy subjects and cardiovascular patients. In a larger study, Werner et al. [27] have reported that $CD34^+KDR^+$ cell count predicted cardiovascular events and cardiovascular death during a 12-month follow-up in 519 patients with coronary artery disease (CAD). Also, in a subset, colony-forming units (CFUs) predicted cardiovascular events. Furthermore, Hill et al. [28] reported a strong correlation between the number of circulating endothelial progenitor cells (measured as CFUs) and the subjects' combined Framingham risk factor score. Also, the measurement of flow-mediated brachial-artery reactivity revealed a significant relation between endothelial function and the number of progenitor cells. Indeed, levels of circulating EPCs were a better predictor of vascular reactivity than was the presence or absence of conventional risk factors [29]. Fadini et al. showed that a low CD34 count, a measure of progenitor cells, in addition to MetS was associated with increased cardiovascular events (CVEs). Fadini's group have also shown an association between EPC reduction and increased carotid intima media thickness (c-IMT), as a marker of early atherosclerotic remodeling in healthy subjects [30,31].

EPC functionality is determined by its capacity to form colonies, migration, and ability to form tubules. In addition to flow cytometric quantitation of CD34/KDR predicting CVE, functional assays such as CFU and EPC migration have been shown to correlate significantly with CAD risk factors, severity, and events [29].

Thus, the measurement of EPCs may be a surrogate biologic marker for vascular function and cumulative cardiovascular risk, suggesting further that endothelial injury in the absence of sufficient circulating progenitor cells may unfavorably affect the progression of CVD. Furthermore, decrease in circulating EPCs contributes to impaired angiogenesis as well as progression of atherosclerosis and patients at risk for CAD have a decreased number of circulating EPCs with impaired activity. Thus, it seems important that both the number and functional activity of EPCs should be investigated. The individual components of the MetS are associated with impairment of EPC number and function.

EPC and MetS

With regards to the MetS, there is limited data on EPC number and functionality. In the study by Westerweel et al. [32] they show that circulating $CD34^+KDR^+$ EPC levels were reduced by nearly 40% in obese men with MetS compared to nonobese men. Although this was a small study that included 19 patients with MetS, it is important to emphasize that in this study, they excluded patients with overt clinical CVD or diabetes. They did not study EPC functionality. In the study by Jialal et al. [33], they reported on EPC number and functionality in a larger sample size of subjects with MetS ($n = 46$, without the confounding factor of diabetes or cardiovascular disease) of which 77% were female and matched controls ($n = 31$). In accord with the study in obese males, they showed a significant decrease in EPC number, also defined by CD34/KDR dual positivity. Furthermore, these investigators also looked at functionality of EPCs such as CFUs, migration, and tubule formation. In addition to the reduction in numbers, they showed that there was significant impaired clonogenic capacity and also an impaired capacity to incorporate into tubule structures. Whilst there was a decrease in migration of the EPCs in MetS this did not attain significance. It needs to be emphasized that none of the subjects were on medications that affect EPCs suggesting that the defect in EPCs manifests early in nascent MetS prior to the development of diabetes or CVD. Fadini et al. [30] have reported in a study decreased circulating EPCs and progenitor cells in diabetic patients with peripheral vascular disease. In this paper, they did a subgroup analysis of MetS patients versus non-MetS patients. However, not much detail is provided with respect to coexistent diseases and morbidity such as diabetes and peripheral vascular disease or concomitant medications in these two subgroups. In a subsequent report by Fadini et al. [31], they showed that in patients with MetS, there was a decrease in progenitor cells ($CD34^+$ cells). It appears that many of these patients also could have diabetes, and be on medications such as statins, angiotensin-converting enzyme inhibitors (ACE-I), angiotensin receptor blockers (ARBs), and antidiabetic therapy such as pioglitazone, which could have influenced the data. Previously, Satoh et al. have reported an increased EPC number

in CAD patients with MetS and without MetS [34]. They did not compare patients with MetS with controls and their sample sizes were small ($n = 15$ for acute myocardial infarction and $n = 16$ for patients with stable angina pectoris and MetS, respectively). Interestingly, they also showed increased oxidative DNA damage, decreased telomerase activity, and decreased telomere length, a marker of increased senescence in EPCs of CAD patients with MetS than the CAD patients without MetS. This suggests that the increase in EPC with CVD was a dysfunctional population since EPCs are generally well endowed with antioxidant defenses. Other functional measures of EPC activity such as tubule formation or CFUs or adhesion were not investigated in this study. Thus, this needs to be investigated further. Recently, La Vignera et al. [35] reported increased EPCs in patients with arterial erectile dysfunction and MetS compared to controls. Furthermore, the increased EPC in their subjects correlated with EMPs and IMT suggesting that this is a dysfunctional population. However, they did not study EPC functionality.

MetS is a proinflammatory state. In the study by Jialal et al. [33], they showed significant correlation of CRP levels in MetS with decreased EPC number and functionality, pointing to the role of inflammation in this process.

There is limited data with regards to mobilizing factors in patients with MetS. Egan et al. [36] have reported the profound reduction in EPCs due to impaired mobilization from bone marrow because of the lower expression of CXC chemokine receptor 4 (CXCR4+)/CD34+ cells in diabetics versus controls. Importantly, CXCR4, CD117, and KDR are defined as the mobilizing receptors for progenitor cells (PCs). Jialal et al. recently showed in subjects with MetS ($n = 36$) compared to age- and gender-matched controls ($n = 38$) that there was a significant reduction of 83% in granulocyte colony-stimulating factor levels in patients with MetS [37]. Also, there were decreases in SCF and SCF soluble receptor levels. However, there was no significant difference in stromal cell-derived factor-1 levels, and paradoxically, vascular endothelial growth factor levels were increased, consistent with VEGF resistance, which has been reported previously with insulin-resistant states such as diabetes and MetS.

In conclusion, EPC number and functionality could serve as an additional novel cellular biomarker of endothelial integrity and impaired neoangiogenesis in patients with MetS who clearly have manifest endothelial dysfunction [38]. Prospective studies should demonstrate that they predict CVD. Thus, EPC number and/or functionality could emerge as a novel cellular biomarker of CVD risk and could better inform clinicians about potential pharmacotherapy for patients with MetS.

Conclusion

Thus, this review of the literature indicates that endothelial dysfunction is pronounced in MetS and while there is much variability in the study of endothelial dysfunction by

flow-mediated dilatation, several new cellular markers such as endothelial microparticles and endothelial progenitor cells may emerge as novel biomarkers of endothelial function, which can also be used to test management/pharmacotherapy of MetS, as it relates to vascular dysfunction.

CHAPTER 72

Hemostatic abnormalities in diabetes mellitus

R.A. Ajjan and Peter J. Grant

Division of Cardiovascular and Diabetes Research, University of Leeds/Leeds Teaching Hospitals Trust, Leeds, UK

Key points

- Diabetes is a chronic progressive metabolic state characterized by the presence of inflammatory thrombotic changes that promote vascular damage.

- In insulin-resistant states, suppression of fibrinolysis due to elevated levels of the fibrinolytic inhibitor, plasminogen activator inhibitor-1, is an invariable finding. Elevated levels of fibrinogen and other clotting factors are also seen.

- Hyperglycemia further inhibits lysis by inducing qualitative changes in coagulation and fibrinolytic factors altering protein activity and generating a fibrin clot resistant to lysis.

- The platelet responds to the complex metabolic milieu associated with advanced diabetes by developing enhanced activation, increased aggregatory and adhesive properties and interacting with monocyte/macrophages to promote an inflammatory thrombotic environment.

- Disturbances in circadian rhythm may provide an important link between obesity, inflammation, and abnormalities in thrombosis.

- Interventions that ameliorate insulin resistance and hyperglycemia have potentially beneficial effects on the abnormalities in coagulation/fibrinolysis, and platelet function seen in diabetes.

Introduction

Hemostatic mechanisms in man have a primary physiologic function to arrest bleeding in the context of trauma and vascular damage, with a secondary role in vascular repair. Interactions between the fluid and cellular phases of thrombotic pathways (coagulation/fibrinolysis and platelets) and the inflammatory system (complement, cytokines, macrophages) are important in integrating thrombotic and anti-infective processes in these situations. Abnormalities in hemostasis are associated with a bewildering array of bleeding disorders, primarily linked to deficiencies in clotting factors and platelets, and a range of thrombotic diseases affecting both the venous and arterial systems.

Plasma levels and/or activity of components of coagulation/fibrinolytic pathways and platelets are regulated by a wide variety of genetic and environmental influences, the latter including the direct effect of post-translational modifications and the indirect influence of other factors such as dyslipidemia, smoking, insulin resistance, and obesity. Diabetes mellitus is itself associated with a plethora of metabolic changes many of which interact with components of the hemostatic system to increase thrombotic risk which clinically manifests with increased rates of myocardial infarction, thrombotic stroke, peripheral vascular disease, and venous thrombosis.

Occlusive thrombotic vascular disease is a major cause of morbidity and mortality in subjects with diabetes and the majority of patients with diabetes ultimately die from vascular causes. Arterial disease is characterized by the early development of endothelial dysfunction and fatty streaks followed by the development of arterial plaques, and finally occlusive thrombus formation on a ruptured, unstable plaque. Diabetes affects all aspects of these processes and clinical studies indicate that coronary artery plaques from subjects with diabetes have increased plaque thrombus and monocyte/macrophage infiltration compared to nondiabetic controls. This together with more extensive disease affecting both the proximal and distal coronary vasculature describes a situation in which the circulation supplying the heart has more lesions, with a greater propensity to rupture and to produce more thrombus. Arterial thrombus is characterized by the development of a platelet-rich fibrin mesh, whilst venous thrombosis is characterized by a fibrin-rich, platelet-poor thrombus. Type 2 diabetes (T2DM) is associated with increased platelet activation and a range of abnormalities in coagulation and fibrinolysis related to the metabolic abnormalities associated with insulin resistance and hyperglycemia [1]. These prothrombotic changes contribute to

---

the increased prevalence and severity of acute coronary syndromes and other arterial disorders. Increased platelet reactivity in particular has been reported to prospectively predict risk of major adverse cardiovascular events in T2DM patients with stable coronary artery disease [2]. Most evidence seems to indicate that thrombotic disorders appear with the development of insulin resistance and in the presence of complications such as microalbuminuria and chronic kidney disease [3,4]. Glycemia has an additional effect on many of these processes which tend to deteriorate as the chronic nature of diabetes unfolds. Clinical studies suggest that as a consequence uncomplicated T1DM has relatively minor alterations in thrombotic profile, whilst nondiabetic insulin-resistant relatives of subjects with diabetes have clustering of inflammatory thrombotic risk prior to the appearance of frank hyperglycemia [5,6] and in both groups further changes occur as the disorder progresses.

The recognition that myocardial infarction usually results from thrombus formation on a ruptured plaque has led to a revolution in therapeutic approaches which has improved primary and secondary prevention of cardiovascular disease as well as the management of acute coronary syndromes. Amongst these, the development of increasingly sophisticated inhibitors of platelet activation, direct thrombin inhibitors and heparin-like molecules have transformed care of both diabetic and nondiabetic subjects with coronary artery disease. In this chapter we will describe the mechanisms that underpin abnormalities in platelet function and the fluid phases of coagulation/fibrinolysis in subjects with diabetes and the way in which these changes relate to cardiovascular disease.

Mechanisms of thrombosis

The hemostatic system

The hemostatic system consists of a fluid phase of activators and inhibitors of coagulation and fibrinolysis which regulate the formation and breakdown of fibrin and a cellular, platelet phase which interacts with sites of vascular damage and fibrin to release a range of procoagulant and inflammatory mediators. The interaction between the fluid and cellular phase of coagulation is crucial to maintaining a normal hemostatic environment and thrombin is the pivotal enzyme with a key role in both fibrin formation and platelet activation. Thrombin is generated by the cleavage of prothrombin by a Factor Xase complex which occurs as the result of interactions between tissue factor, activated Factor VII and Factor X secondary to vascular damage. Thrombin, whilst having major procoagulant and pro-inflammatory effects, can express an anticoagulant effect when thrombin binds to the cell-associated receptor thrombomodulin, which modulates clot resistance to fibrinolysis.

Fibrinogen

The insoluble fibrin network, forming the backbone of the blood clot, is derived from the soluble fibrinogen molecule. Fibrinogen is a large protein produced by the liver which consists of two sets of α, β, and γ chains linked by disulfide bonds. Thrombin cleaves fibrinogen by cutting small fibrinopeptides from each of the fibrinogen α chains allowing the α chains to open out and interact with other cleaved fibrinogen molecules leading to the formation of double-stranded fibrils which branch out to create a complex fibrin network [7]. Cleavage of fibrinopeptide B allows lateral aggregation of the developing fibrin structure. The fibrinogen molecule has another important role in thrombotic processes, acting as a ligand for the activated platelet GpIIb/IIIa receptor. Binding to this receptor facilitates platelet/platelet interactions and platelet aggregation.

Factor XIII activation and fibrin cross-linking

Coagulation FXIII is a transglutaminase which circulates in plasma in a heterodimeric structure that consists of two A- and two B-subunits. Thrombin activates Factor XIII by cleaving a 37 amino acid peptide from the A subunit which promotes separation of the A- and B- subunits and permits exposure of the active site on FXIIIA. Activated Factor XIIIA covalently cross-links fibrin fibrils and various antifibrinolytic proteins to the clot which creates a fibrin network with altered mechanical properties and increased resistance to fibrinolytic activity [8].

Fibrinolysis

Analogous to thrombin, plasmin is the pivotal enzyme in the fibrinolytic cascade. Plasmin is generated by the cleavage of plasminogen by tissue plasminogen activator (tPA) and this reaction occurs 1000-fold faster in the presence of fibrin [9]. A lysine binding site on plasmin binds plasmin to fibrin which facilitates fibrin breakdown and also protects plasmin from local inhibition by antiplasmin. Plasmin cleaves arginine and lysine sites on a range of molecules and its activity is tightly controlled by antiplasmin to prevent systemic proteolysis. Cleavage of fibrin by plasmin leads to the generation of fibrin degradation products. Fibrin degradation products in turn can be measured in plasma, and one of which, D-dimer, is used as an indicator of the presence of venous thrombotic disease [10]. In addition to antiplasmin, other inhibitors of this pathway include plasminogen activator inhibitor-1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI). PAI-1 is the fast-acting inhibitor of tPA which binds to and inhibits tPA activity. PAI-1 is produced by endothelial cells, platelets liver and adipose tissue, and circulates in plasma in excess over tPA and is also found in fairly high concentrations in thrombus [1]. TAFI is found in large quantities in platelets and plasma and is activated by thrombin, a cleavage event that is much enhanced when thrombin is bound to thrombomodulin. Activated TAFI cleaves the N-terminal lysine residues from degrading fibrin to prevent binding of plasminogen to fibrin, consequently resulting in inhibition of plasmin generation and clot lysis.

Platelet activation

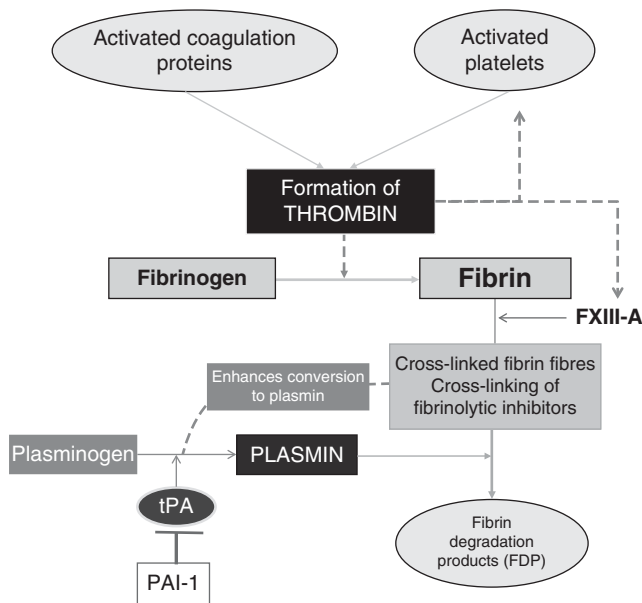
Damage to the vascular wall leads to two key events in platelet-associated clot formation: (1) receptor-mediated


Figure 72.1 Formation of the fibrin clot and fibrinolysis. Injury to the vessel wall results in platelet aggregation and activation of the coagulation pathway culminating in thrombin production. Thrombin cleaves the fibrinogen molecule transforming the soluble protein into an insoluble network of fibrin fibers. Thrombin-activated factor (F)XIII further stabilizes the fibrin clot by cross-linking fibrinogen chains and enhances resistance to fibrinolysis by cross-linking various antifibrinolytic proteins including plasminogen inhibitor and thrombin-activatable fibrinolysis inhibitor. Plasmin, generated from plasminogen by tissue plasminogen activator (tPA), is the main protein responsible for clot lysis, resulting in the generation of fibrin degradation products, one of which is D-dimer. The fibrinolytic process is closely controlled by plasminogen activator inhibitor (PAI)-1 and increased levels of this protein can result in a pathologic hypofibrinolytic environment, commonly seen in insulin-resistant states including type 2 diabetes.

platelet adherence and aggregation, and (2) thrombin-mediated platelet activation. Adherence to the subendothelial matrix is facilitated by a range of glycoprotein receptors (GP Ib/IX, GPVI, and GPIa) which interact with von Willebrand factor to promote platelet adhesion. This interaction leads to activation of platelet GPIIb/IIIa which binds fibrinogen and promotes platelet aggregation. Thrombin is the most potent platelet activator which exerts its effects through binding to protease-activated receptor 1 (PAR-1) on the platelet surface. This leads to a cascade of signaling processes culminating in the release of a range of inflammatory and thrombotic mediators that further promote clot formation. In addition to thrombin, a range of other mediators including ADP, collagen and thromboxane can activate the platelet through a receptor binding event. These receptors provide some of the novel targets for therapeutic approaches discussed later and described in a number of excellent reviews [11,12]. A summary of fibrin clot formation and lysis following vascular damage is provided in Figure 72.1.

Summary

An important characteristic of thrombotic processes is the closely regulated interactions between soluble circulating proteins involved in coagulation/fibrinolysis and the cellular component of coagulation. In addition to platelets, thrombosis involves binding events on endothelium, the exposed subendothelial layer, macrophages and leukocytes with the balance between thrombosis and clot lysis and the localization of clot formation depending on these interactions. Emerging evidence demonstrates the importance of thrombotic inflammatory interactions, both at the cellular level where platelet/macrophage binding initiates the release of a range of soluble procoagulant and inflammatory molecules and in the fluid phase where, for example, complement C3 binds fibrin to inhibit fibrinolysis [13]. As these events cycle towards fibrin formation and fibrin/platelet interactions, further levels of control are exerted by the interaction of activators and inhibitors of lysis on fibrin itself. All these levels of control direct and limit thrombus formation and fibrinolysis to the site of damage to prevent systemic thrombus formation and proteolysis.

Mechanisms of thrombosis in diabetes

Fibrinolysis

The fibrinolytic process is influenced both by the structure of the fibrin network, as compact clots are more difficult to lyse, and abnormalities in fibrinolytic proteins.

Plasminogen activator inhibitor-1 (PAI-1)

The major consistent hemostatic abnormality observed in insulin-resistant T2DM is marked suppression of fibrinolysis associated with increased levels of both PAI-1 and tPA [14]. Studies of euglycemic first-degree relatives of subjects with T2DM indicate that such individuals tend to be insulin resistant and have raised tPA and PAI-1 before a diagnosis of diabetes is made, indicating that glycemia per se is not the main factor responsible for altered protein levels. The Insulin Resistance Atherosclerosis Study reported that early increases in PAI-1 in subjects with the metabolic syndrome predicted conversion to T2DM and suggested that high PAI-1 may be a marker for risk of developing the metabolic syndrome. In the Leeds Family Study of clinically healthy individuals, clustering of conventional risk factors was associated with progressive suppression of global tests of fibrinolysis that was related to the number of risk factors an individual held [15]. These findings in a randomly selected cohort of families support the view that increases in PAI-1 occur early in the course of the development of cardiovascular disease. The PAI-1 gene has a 4G/5G polymorphism 675 bp from the start site and the 4G allele has been associated with both higher PAI-1 levels and increased risk of acute coronary syndrome [16]. Additionally there are indications that interactions between the 4G/5G genotype and triglyceride generate a nuclear complex that regulates PAI-1 expression providing a mechanism for increasing cardiovascular risk [17]. In nondiabetic populations the link to cardiovascular risk is provided by prospective studies indicating that elevated PAI-1 predicts the development of

myocardial infarction, and gene association studies which relate the 4G allele in the PAI-1 gene to history of cardiovascular disease. However, there are considerable inconsistencies in the literature regarding these associations with both positive and negative studies. Authors have tried to explain this by various means including a requirement for PAI-1 to have the presence of additional risk factors (the ECTIM study) and a potential effect of the PAI-1 gene on cholesterol metabolism [18]. In a small study of 160 subjects with T2DM, the PAI-1 4G allele was significantly more common in the 38 subjects with clinical evidence of coronary artery disease. In modern terms, this is a tiny case control study and the results may represent skewed data. In nondiabetic patients with acute stroke no association was found between PAI-1 genotype and thrombotic stroke and in 40 T2DM subjects with acute stroke compared to 80 non-stroke T2DM measures of circulating parameters of fibrinolysis did not suggest an association between suppression of lysis and cerebrovascular disease.

The range of cell lines that produce PAI-1 has produced a variety of results that have largely not been reproduced in clinical studies. *In vitro* PAI-1 synthesis and secretion can be induced by insulin, insulin like growth factor-1, triglyceride, and glucose. In Hep G2 cells, insulin is reported in some, but not all, studies, to increase PAI-1 expression. Synergistic responses have been reported with insulin and a combination of triglyceride and free fatty acids in Hep G2 cells, a finding reproduced in human subjects [19,20]. One of the most interesting developments in this field has, however, related to the potential role of obesity and the adipocyte in regulating PAI-1 expression. Human adipocytes *in vitro* express PAI-1 in response to insulin, angiotensin II, fatty acids, and TNFα. The addition of the TNFα inhibitor pentoxifylline to adipocytes decreases basal PAI-1 expression to suggest that autocrine regulation of PAI-1 by adipocyte TNFα may be important, linking adipocyte inflammatory responses to thrombotic risk [21]. This hypothesis was partially tested *in vivo* using open heart surgery as a model of a severe inflammatory response and in this study 27-fold increases in PAI-1 gene expression were seen in omental fat cells and threefold increases in subcutaneous fat cells. This increase in gene expression was associated with an increase in circulating PAI-1 levels [22]. Further sophistication of this model has been generated by the role of the macrophage in adipocyte responses. It is now established that in obesity the fat cell mass is infiltrated by macrophages that are activated by overspill of free fatty acids from the adipocyte and which in response release a range of cytokines, including TNFα to stimulate adipokine expression, including PAI-1 [23]. These findings provide further support for the emerging view that inflammatory thrombotic interactions at the cellular and protein level underpin many of the critical processes that generate atherothrombotic risk in diabetes.

Thrombin-activated fibrinolysis inhibitor (TAFI)
TAFI levels seem to be unaffected by insulin resistance or hyperglycemia, although there are indications that levels are increased in T2DM with microalbuminuria [24].

Plasminogen activation
We have recently observed that inhibition of fibrinolysis in poorly controlled diabetes is partially reversed by relatively minor improvements in glycemia (around 1% decrease in HbA1c), an effect independent of PAI-1 [25]. We have demonstrated that deranged lysis in diabetes is partly related to impaired plasmin activation secondary to increased protein glycation and that this can be ameliorated by improving glycemic control, consequently resulting in improved plasmin activity and fibrinolysis [26]. These observations suggest that management of lifestyle, weight loss, insulin resistance, and glycemia all benefit the hypofibrinolytic state observed in subjects with diabetes.

Coagulation
The coagulation process involves a number of protein interactions, which were briefly discussed earlier, and a more detailed description of this process can be found elsewhere [27]. The role of key coagulation proteins in atherothrombosis is discussed later.

Factor VII
Factor VII is a vitamin K-dependent serine protease synthesized in the liver which is activated by tissue factor released from damaged tissue and which has a key role in activation of the coagulation cascade and conversion of prothrombin to thrombin. In a manner similar to that seen with PAI-1, FVII levels show an association with insulin resistance and T2DM, with increased levels described in healthy individuals with the metabolic syndrome, first-degree relatives of T2DM patients and in type 2 diabetes itself [1]. Regulation of FVII appears to take place through the effects of triglyceride-rich particles and in clinical studies levels of FVII correlate with plasma triglycerides. It has been postulated that deficient postprandial catabolism of triglyceride may prolong the half-life of FVII, thereby increasing levels, and/or that triglyceride binds and activates FVII [1]. The role of FVII as in independent predictor of cardiovascular events is open to question although the 16-year follow-up of the Northwick Park Heart Study reported a significant association between elevated FVII and fatal cardiac events.

Fibrinogen
Plasma levels of fibrinogen influence clot formation (see later), blood flow, and platelet aggregation and elevated levels are a consistent cardiovascular risk factor in both diabetic and non-diabetic populations [28]. Although the relationship between fibrinogen and features of the insulin resistance syndrome is weaker than for PAI-1 and FVII, consistent associations exist with insulin levels, BMI, and reduced HDL [1]. Fibrinogen levels are elevated in healthy first-degree relatives of patients with T2DM and in T2DM in both Caucasian and Asian subjects [29]. A positive correlation has been reported between fibrinogen and glycemic control, although improvements in glycemia do not consistently reduce fibrinogen levels. Glycation of fibrinogen occurs on lysine residues in the β- and γ-chains of fibrinogen, an affect which appears to alter fibrin structure/function (see fibrin,

later) but not acetylation by aspirin [30]. Metformin and thiazo-lidinedione therapy in T2DM leads to a fall in fibrinogen, in support of insulin resistance regulating fibrinogen expression [26].

FVIII/von Willebrand factor (vWF)

Synthesized by endothelial cells and megakaryocytes, vWF has an important role in protecting and therefore increasing the half-life of Factor VIII in the circulation. vWF acts as a ligand for the Gp-Ib platelet receptor and acts to tether platelets to the collagen-rich subendothelial layer exposed by vascular damage. Analogous to the platelet aggregation effects of fibrinogen, vWF enhances platelet adhesion and these two proteins have a crucial role in the formation of a platelet-rich clot characteristic of arterial disease. Coagulation Factor VIII is a component of the contact activation pathway, deficiency of which leads to hemophilia. Evidence indicates that both FVIII and vWF associate with features of the metabolic syndrome [31] and may have a role in arterial disease, although as with other coagulation factors, independent associations are open to question.

Factor XII

Factor XII is a serine protease derived from the liver and involved in the early stages of contact activation of the coagulation cascade with additional roles in complement activation, fibrinolysis, and the kinin system. Levels of Factor XII correlate with some features of the metabolic syndrome including triglyceride [32]; as with Factor VII there is evidence that triglyceride activates Factor XII.

Fibrin structure in diabetes

Activation of the coagulation cascade and the generation of thrombin with formation of cross-linked fibrin is an important component of occlusive thrombus. Increased levels of coagulation factors, particularly fibrinogen, with enhanced thrombin generation, will tend to produce a fibrin structure that is denser and more tightly packed [14]. This structure, independent of the changes in levels of lytic proteins described earlier, is more resistant to lysis and is less elastic, generating a rigid thrombotic mesh. In addition to the effects of coagulation proteins, studies in subjects with diabetes using purified fibrinogen, clearly indicate that post-translational modifications to the fibrinogen molecule, which could include glycation, oxidation or phosphorylation also affect clot structure adversely. Clots formed from purified fibrinogen of individuals with T2DM show reduced permeability, indicating more compact clots, which correlated with HbA1c levels and hence glycemic control [33]. Jörneskog reported changes in clot structure in T1DM subjects showing reduced permeability to indicate a more compact structure [34]. Furthermore, fibrin generated from purified fibrinogen in subjects before and after improvements in glycemic control demonstrates reversal of the adverse changes in fibrin structure/function and although this might superficially point to glycation as the cause, this is difficult to establish definitively [35]. Molecular studies of purified fibrinogen from subjects with T2DM indicate that the predominant abnormality

associated with the change in clot structure is inhibition of fibrinolysis. Under these circumstances the equilibrium binding affinity for both tPA and plasminogen with fibrin was reduced and as a consequence, plasmin generation on the clot surface was markedly impaired. In addition, FXIII-induced cross-linking of antiplasmin to fibrin was also enhanced tending to further inhibit plasmin generated on the clot surface [36]. The evidence indicates that post-translational modifications to fibrin(ogen) are promoting structural alterations to fibrin [37]. However, such changes facilitate decreased plasmin generation on the clot surface and increased antiplasmin binding with an overall effect on fibrinolysis rather than clot formation [36]. Compact structures have been associated with increased cardiovascular risk and poorer cardiovascular outcome in nondiabetic populations and it is likely that a range of metabolic influences affect this phenotype.

The platelet in diabetes

The circulating platelet is sensitive to a wide range of metabolic changes associated with diabetes. Hyperglycemia increases platelet reactivity and improvement in glycemic control ameliorates these effects. It has been proposed that hyperglycemia may have osmotic effects on the platelet, alter protein kinase C expression and/or have indirect effects through exposure to glycated proteins. In this respect, evidence indicates that AGE proteins induce a prothrombotic state through interactions with the platelet CD36 receptor mediated by a JNK2 pathway [38]. Oxidized LDL is reported to activate platelets in insulin-resistant subjects [39] and CD36 is involved in platelet activation through interactions with dyslipidemia and oxidative stress, effects which are absent in CD36 null mice [40]. It is of note that the macrophage CD36 receptor is established as having a role in the formation of early fatty streaks through interactions with oxidized LDL leading to increased foam cell formation. This response in macrophages is accentuated in insulin-resistant states and ameliorated by thiazolidinediones, agents that are reported to possess antiplatelet effects, although it is not known whether this effect is mediated through platelet CD36. Other potential influences include effects of insulin resistance. Insulin has anti-aggregatory effects in platelets from insulin-sensitive subjects and emerging data indicate that IGF-1 may have prothrombotic effects on the platelet through interaction with the hetrodimerized insulin/IGF-1 receptor in insulin-resistant states. In a population of 208 T2DM patients with stable coronary artery disease followed up for 24 months, carriers of a particular insulin receptor substrate-1 (IRS-1) genotype exhibited both increased platelet reactivity and a significantly higher risk of major adverse cardiovascular events [41]. These findings both implicate the insulin signaling pathway in cardiovascular outcomes and provide a potential mechanism for interindividual differences between subjects with diabetes.

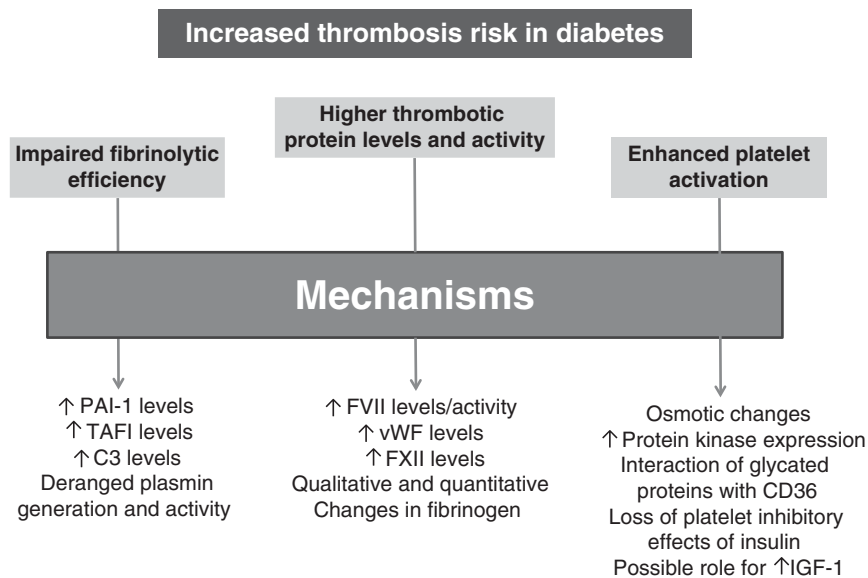
Overall the available data indicate that diabetes is associated with a range of metabolic abnormalities that adversely influence platelet function. Management of the platelet aspect of


Figure 72.2 Pathways leading to increased thrombosis risk in diabetes. A thrombotic environment in diabetes results from enhanced platelet activation, increased coagulation factor levels and activity coupled with impaired fibrinolysis, by mechanisms that involve various proteins as shown. PAI, plasminogen activator inhibitor; TAFI, thrombin-activatable fibrinolysis inhibitor; C3, complement C3; vWf, von Willebrand factor; IGF, insulin-like growth factor.

this prothrombotic state should involve normalization of the metabolic changes seen in diabetes and the appropriate use of antiplatelet therapy as discussed later.

The mechanistic pathways responsible for increased thrombosis potential in diabetes are summarized in Figure 72.2.

The effects of glucose and glycation on thrombosis

The progressive nature of both T1 and T2DM tends to culminate in common metabolic changes which include insulin resistance, varying degrees of β-cell failure, and hyperglycemia, which directly affect thrombosis potential and which have been recently reviewed [42]. Attempts to dissect out the relative contributions of hyperglycemia and hyperinsulinemia to thrombotic phenotypes have been carried out *in vivo* using various clamp techniques and *in vitro* by assessing effects on proteins and cell systems involved in thrombosis. Employing hyperglycemic clamps, it has been reported that there are associated increases in thrombin–antithrombin complexes and soluble tissue factor [43]. In the same study hyperinsulinemic euglycemia was associated with increases in PAI-1. The latter findings are in agreement with some studies which report increased synthesis and secretion of PAI-1 from cells stimulated with insulin, findings which are not, however, consistent with all *in vitro* or *in vivo* studies. There are suggestions that LDL- and VLDL-induced increases in PAI-1 are augmented by glycation of apoproteins [44], and this could potentially explain some of the inconsistencies found in clinical

studies if similar mechanisms applied to the effects of insulin stimulation. As described earlier, both plasmin generation and fibrin structure are modified by glycation with further reductions in lysis and the generation of a fibrin structure that is resistant to lytic degradation. Improvements in glycemic control enhance plasmin generation [26] and a combination of improved glycemic control and vitamin C reductions in oxidative stress is reported to ameliorate increased thrombin generation in T1DM [45]. Both hyperglycemia and glycation appear to have a role in monocyte and platelet activation, important components of the cellular phase of thrombosis. In nondiabetic subjects, platelet CD40L expression was increased by hyperglycemia as were the prevalence of monocyte/platelet aggregates and monocyte tissue factor expression in the presence of combined hyperglycemia/ hyperinsulinemia [46]. A potential mechanism for the direct effects of glucose on platelets comes from identification of glucose-regulated aldose reductase stimulation of platelet thromboxane which would potentially have pro-aggregatory effects on the platelet *in vivo* [47]. Glycation also increases tissue factor expression in both monocytes and endothelial cells and studies in the Badimon chamber, which measures *in vivo* thrombosis by passing blood over a porcine artery, support the concept that changing levels of glycation alter tissue factor expression [48]. Overall, the evidence indicates that the metabolic milieu associated with diabetes, including hyperglycemia, glycation, oxidative stress, and hyperinsulinemia have the capacity to interact at all levels with the fluid and cellular phases of thrombosis to increase thrombotic risk and the clinical presentation of cardiovascular disease.

Inflammatory, thrombotic interactions

Multiple strands of evidence link inflammation and thrombosis as interrelated systems that are physiologically active in coordinating responses to trauma to prevent bleeding and infection. Cellular components of both systems (monocyte/macrophage and platelet/endothelium) share common pathways of activation, features of which are common to diabetes (hyperinsulinemia, glucose/glycation, dyslipidemia, oxidative stress) and there is substantial evidence indicating that inflammation/thrombosis is important in the pathogenesis of both diabetes [49] and cardiovascular disease [50]. Platelets have an important role linking inflammation and thrombosis interacting with inflammatory cells and the vascular endothelium [51]. The monocyte/macrophage forms aggregates with platelets activated at the site of vascular injury which leads to the release of a range of soluble inflammatory/thrombotic factors that contribute to hemostasis and thrombosis [52]. Increased monocyte/platelet aggregates occur in subjects with coronary artery disease [53] and are a feature of diabetes. In addition to the cellular aspects, a range of inflammatory cytokines promote release of prothrombotic elements, including PAI-1, to enhance thrombus formation and inhibition of clot lysis [54]. At the level of clot formation, proteomic analysis of fibrin clots demonstrates binding of a wide range of around 20 inflammatory proteins, including complement C3, factor H, and carboxypeptidase N catalytic chain [13]. Complement C3 binds avidly to both fibrinogen and fibrin and prolongs clot lysis, an effect exacerbated by the presence of diabetes [25]. Key interactions between the thrombotic and inflammatory pathways are highlighted in Figure 72.3.

Circadian regulation of thrombotic mechanisms

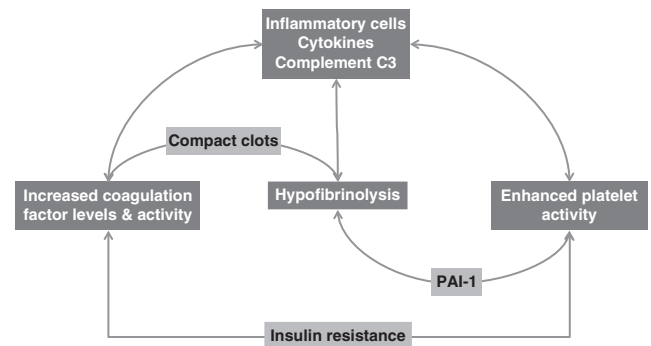
Regulation of metabolic and cellular functions in relation to day/night exposure (circadian variation) and the seasons (circannual variation) is a fundamental biologic feature of life on earth. The central hypothalamic and peripheral clock regulate a wide range of physiologic processes including the cardiovascular, metabolic, hemostatic, and reproductive systems in response to light and food intake to integrate function with the varying requirements imposed by a circadian life. It has been proposed that disruption of circadian responses in man secondary to chronic obesity and loss of daily and seasonal circadian cues is related to the increased risk of developing both diabetes and cardiovascular disease upon adopting Western lifestyles [55]. The central clock is comprised of a series of activators and inhibitors which set up cyclical expression in response to variation in light exposure and which generate core outputs that regulate peripheral tissue clocks. The first recognized component of the


Figure 72.3 Interactions between the thrombotic and inflammatory systems. Cellular components of both systems share common pathways of activation, which include features of insulin resistance. The inflammatory cells and their products, including cytokines and complement C3, contribute to hemostasis and thrombosis. The cellular and fluid phase of coagulation, both of which are modulated by inflammatory products, further interact augmenting the prothrombotic milieu in insulin-resistant states and type 2 diabetes.

clock was termed Clock and this protein forms a heterodimer with BMal 1, to activate other core clock components including BMal 2, Cry1, Cry2, Per1, and Per2. Mutations in the Clock gene have been associated with a diabetes phenotype in mice and with the metabolic syndrome [56] and sleep disorders in man. Aronson suggested that abnormal circadian rhythms in diabetes may be responsible for increased thrombotic risk [57] and since then a body of work has appeared to support this view. At around the same time, it became apparent from *in vitro* studies that the Clock/BMal heterodimer regulated PAI-1 gene expression through interactions with the PAI-1 gene E-box [58]. Murine studies have since confirmed the importance of Clock in fibrinolysis; Clock knockout, whether by disruption of the gene [59] or by sRNA [60] is associated with a fall in plasma PAI-1 levels and shortening of the euglobulin clot lysis time to indicate enhanced fibrinolysis. Cheng et al. [60] reported an associated increase in FVII with prolongation of the prothrombin time and activate partial thromboplastin time to suggest an additional antithrombotic effect, whilst Ohkura et al. reported no changes in prothrombin time, FVII, FX or fibrinogen. Several studies have implicated obesity in disorders of circadian rhythm and in 2006 Oishi [59] reported that Clock was involved in the regulation of PAI-1 in obesity, opening the door for a link between obesity, diabetes and cardiovascular disease through circadian rhythms and PAI-1 gene expression. Evidence to support this was also provided in animal studies implicating Clock in the upregulation of PAI-1 associated with diabetes in streptozotocin-induced murine models [61]. Studies of other core clock genes have reported that the BMal1 murine knockout is associated with increased vWF, fibrinogen, and PAI-1 [62] and that Per 2 attenuates obesity-related inhibition of fibrinolysis by reducing PAI-1 in a BMal-dependent manner [63]. Cry1 and Cry2 knockout mice had no effect on fibrinolysis or thrombotic measures [64].

Although generally less well studied, the work that has been carried out on platelets shows a similar circadian rhythm to that seen for fibrinolysis. In humans, platelet count, activity and platelet markers all show significant diurnal variation with peak levels of activity in the morning [65] corresponding to the commonest time for myocardial infarction. In murine studies, Clock knockout is associated with abolition of diurnal variation in platelet activity and a reduction in platelet numbers to suggest an important physiologic role for Clock in the cellular phase of thrombosis [66]. Per2 knockout mice had almost 50% of normal platelet counts in the peripheral blood and showed decreased aggregation [67]. Studies of the effects of diabetes and/or obesity on circadian regulation of platelet function have not yet been reported.

Ameliorating thrombotic risk in diabetes

Hypoglycemic agents

The importance of insulin resistance in the early manifestations of thrombotic risk is emphasized by studies of insulin sensitizing agents which consistently demonstrate that metformin and thiazolidinedione use is associated with reduction in PAI-1 and tPA plasma levels, whilst metformin has additionally been reported to lower fibrinogen, Factor VII and XIIIA levels and to have direct, potentially beneficial effects on fibrin structure [14]. The most compelling evidence for the longer term benefits of insulin sensitization on thrombotic risk comes from the BARI-2D trial [68]. In this study, over 2300 T2DM patients with stable coronary artery disease were randomized to either an insulin-sensitizing (metformin or glitazone) or an insulin-providing regimen and followed up for 5 years. Striking reductions in PAI-1, tPA, C-reactive protein and fibrinogen were seen at all points in patients treated with insulin sensitizers during the study whilst changes in D-dimer and fibrinopetide A (markers of clot formation and degradation) were similar in the two groups [69]. Baseline values of fibrinogen, D-dimer and C-reactive protein but not PAI-1 or tPA were strongly related to predesignated vascular outcomes. Insulin providers, including the sulfonylureas, have beneficial effects on glucose-mediated alterations in thrombosis; there is as yet very little information on the effects of drugs affecting the incretin system.

Aspirin

In addition to the antiplatelet effects, aspirin acetylates fibrinogen, altering fibrin characteristics [70–72] and may influence clot lysis indirectly through a nitric oxide-dependent mechanism [73,74]. These platelet-independent fibrinolytic properties of aspirin may explain the enhanced fibrinolytic effects of streptokinase when used with aspirin [75]. Aspirin is regularly used in the setting of acute coronary syndrome (ACS), the benefit of which has been repeatedly demonstrated in individuals with or without diabetes [76,77]. Longer term, aspirin is used for secondary cardiovascular protection in diabetes [78,79], a

practice supported by two large meta-analyses [80,81]. The use of aspirin for primary cardiovascular protection in diabetes is more controversial [81,82], with two recent primary prevention studies failing to show an impact of aspirin in diabetes [83,84]. A small study of 651 diabetes subjects over 11.6 years follow-up, reported a reduction in CV events in aspirin-treated subjects after adjustment for significant CV variables, indicating that aspirin may be beneficial in some patients with diabetes [85]. In contrast, an increase in cardiovascular events was reported in aspirin-treated Chinese and Swedish diabetes subjects with no history of ischemic heart disease [86,87]. The reasons for these findings are not clear but may be related to study design (both observational and nonrandomized) and possible antiplatelet treatment of higher risk subjects. Overall, data indicate that the efficacy of aspirin in primary prevention in diabetes is compromised and should be used only in higher risk individuals. Future studies are warranted to fully categorize diabetes subjects who benefit from aspirin therapy for primary cardiovascular prevention.

Clopidogrel

Clopidogrel is a thienopyridine that irreversibly inhibits the platelet P2Y12 receptor. Clopidogrel is a prodrug converted to the active metabolite by the P450 system in the liver and onset of action may be delayed by CYP genetic polymorphisms. Clopidogrel is used in combination with aspirin in subjects with acute coronary syndrome and as monotherapy in those intolerant to aspirin or in patients with symptomatic cerebrovascular disease despite aspirin therapy [88,89].

The combination of aspirin and clopidogrel following ACS has been regularly used in clinical practice supported by a number of studies, with benefits demonstrated in both diabetic and nondiabetic subjects [90–93]. However, newer agents have recently shown a superior efficacy with centers moving gradually away from clopidogrel therapy (detailed later).

Prasugrel

Similarly to clopidogrel, this agent irreversibly blocks the P2Y12 receptor but has a theoretical advantage through quicker metabolism and faster onset of action. Although prasugrel has shown a better efficacy than clopidogrel at reducing ischemic events following ACS, the increase in bleeding risk wiped out the benefit [94]. However, subgroup analysis of the diabetes group showed a benefit without an increase in bleeding risk, an effect that was particularly pronounced in insulin users. This suggests that diabetes subjects have a different response to antiplatelet agents and may require different antithrombotic therapy compared with the nondiabetic population.

Ticagrelol

Ticagrelol blocks the platelet P2Y12 receptor; however, it differs from the thienopyridines described earlier by (i) being an active compound, (ii) reversibility of action, and (iii) shorter half-life necessitating twice daily administration. The PLATO

trial showed superior efficacy of ticagrelol compared with clopidogrel when used in combination with aspirin in 18,642 ACS patients treated medically or following PCI [95]. This agent was equally effective in individuals with diabetes [96], and therefore is becoming the antiplatelet of choice to use in combination with aspirin following ACS in some centers.

Dipyridamol and cilostazol

These agents modulate the phosphodiesterase pathway to reduce platelet activation. Given the absence of an indication for dipyridamol in coronary artery disease and the questionable efficacy in cerebrovascular disease, this agent is not used frequently in clinical practice. In contrast, the use of cilostazol appears to be gaining momentum in diabetes, although large-scale studies are lacking [97,98].

Inhibitors of platelet–fibrinogen interaction

A meta-analysis of GPIIb/IIIa inhibitors, including tirofiban, lamifiban, eptifibatide, and abciximab, suggested superior efficacy of these agents in subjects with diabetes undergoing PCI [99]. However, further studies have given conflicting results in both diabetic and nondiabetic subjects, making routine use of these agents difficult to justify [100,101].

Coagulation inhibitors

Heparin molecules are indirect inhibitors of FX and prothrombin, through modulation of antithrombin III activity. Fractionated heparin is used in ACS, including diabetes. Enoxaparin is the main low molecular weight heparin used because of the predictive anticoagulative effect, ease of injections, and lower risk of thrombocytopenia.

Bivalirudin is a direct thrombin inhibitor recommended for diabetes subjects with ACS in whom coronary intervention is planned, particularly those with a high bleeding risk [102,103]. More work is needed to clarify the characteristics of individuals who would gain most benefit from this therapy. Table 72.1 summarizes the main agents that can influence long-term thrombosis risk in diabetes.

Summary and conclusions

Diabetes mellitus is a chronic condition characterized by the presence of hyperglycemia and an increased risk of cardiovascular disease. Although T1 and T2DM have a distinct pathologic basis, the progressive nature of these disorders tends to lead to convergent characteristics over many years following diagnosis. For example, individuals with T1DM can become insulin-resistant, displaying features of T2DM, whereas individuals with T2DM may progress to β-cell failure, requiring insulin therapy. Inflammatory thrombotic interactions are fundamental to the generation of vulnerable vascular lesions and to the formation of an occlusive thrombus when plaques become unstable and rupture. These interactions are sensitive to a range of metabolic abnormalities associated with both insulin resistance and hyperglycemia/glycation and the progressive nature of diabetes is tracked by progressive changes in risk for vascular damage. Thrombotic processes include the fluid and cellular phases of coagulation, fibrinolysis, and platelet function and all aspects are affected in a potentially deleterious way by diabetes and developing complications. It is important to recognize that occlusive vascular damage occurs over many years and involves a wide range of pathophysiologic processes of which thrombosis is only a part. Just as complex interactions generate a vascular risk profile, so therapeutic interventions that deal with multiple risk factors tend to ameliorate risk. In this respect management of insulin resistance through weight loss, exercise, insulin-sensitizing agents, glycemia/glycation, and lipid lowering will all improve multiple risk factors in addition to their effects on thrombosis. In the presence of acute coronary syndromes the use of antiplatelet agents, direct thrombin inhibitors, and other approaches affecting thrombotic

Table 72.1 The role of different long-term treatment agents in ameliorating the thrombosis risk in diabetes. It should be noted that agents that reduce thrombosis risk can increase the risk of bleeding, whereas hypoglycemic agents can both reduce and increase thrombosis risk depending on blood glucose levels

Ameliorating the thrombotic environment in diabetes using oral therapy		
Agent	**Benefits**	**Risks**
Hypoglycemics	Reduction of protein glycation	Hypoglycemia (which can be prothrombotic)
Aspirin	Reduction in platelet aggregation	Bleeding complications
	Enhanced fibrinolysis	Reduced efficacy in diabetes (unclear mechanisms)
Clopidogrel	Reduction in platelet aggregation	Bleeding complications
		Reduced efficacy in some individuals
Prasugrel	Reduction in platelet aggregation	Bleeding complications
	May be more effective in diabetes	Cost Dual therapy only
Ticagrelol	Reduction in platelet aggregation	Bleeding complications
	Good safety profile	Cost Dual therapy only
Cilostazol	Reduction in platelet aggregation	Side effect profile Triple therapy

processes has radically altered outcomes in both diabetic and nondiabetic subjects.

Perhaps the future in this rapidly changing field lies in a clear understanding of the relationship between obesity-induced changes in circadian rhythm and alterations in thrombotic risk in particular and vascular risk in general. The potential implications for how we live our lives and for ameliorating the effects of modern lifestyles on the current epidemic of diabetes and its complications are currently difficult to estimate. This is likely, however, to continue to be a major area of interest in the coming years.

Key points

- Cardiovascular disease develops frequently in patients with diabetes and is a cause of death in some 70% of these patients.

- Conversely, some 70% of patients with chronic or acute coronary heart disease have diabetes—known or undiagnosed—or prediabetes (impaired glucose tolerance); hence, all patients with established coronary heart disease without known diabetes should be screened for hidden diabetes.

- Cardiac autonomic neuropathy, (functional) microangiopathy, hypoglycemia, cardiomyopathy, and heart failure are specific features in patients with diabetes and impact on the symptomatology, complexity, and prognosis of heart disease in these patients.

- Serious cardiac arrhythmias may occur in the context of high glucose variability or excessive hyper- and hypoglycemia.

- Appropriate intensive multifactorial medical therapy to reduce total cardiovascular risk and consequent guideline-based revascularization therapy are the cornerstones in the management of patients with diabetes and coronary heart disease.

Introduction

Diabetes mellitus and coronary heart disease (CHD) often appear as two sides of the same coin. On the one side, diabetes remains as an independent cardiovascular (CV) risk predictor that still today doubles the risk of CV morbidity and mortality. Some 70% of all patients with diabetes will ultimately die from CV disease (CVD), mostly from cardiac complications, despite all the progress made in interventional and conservative cardiology in recent years [1,2]. On the other side, some 70–75% of all patients with established CHD present with diabetes or significant perturbations of glucose homeostasis.

With a growing tendency, more than 30% of contemporary cardiology patients exhibit coexisting known diabetes. In addition, as many as 10–15% of cardiology patients have previously undiagnosed diabetes and another quarter has impaired glucose tolerance (IGT) or prediabetes, as the Euro Heart Survey [3] and other epidemiologic evaluations have shown. Thus, there is a huge overlap between the two fields of diabetology and cardiology warranting joint action, and in 2007 the first-ever cardio-diabetologic guidelines on diabetes, prediabetes, and cardiovascular diseases were launched by the European Society of Cardiology and the European Association for the Study of Diabetes [4]. Similar joint guidelines have since followed on other continents of the world. This chapter attempts to give a comprehensive summary of the joint cardio-diabetologic approach, describing the clinical features and the treatment of CHD from the perspective of the diabetologist.

Key practical features of the relationship between CHD and diabetes

CHD at onset of diabetes

CHD may be present at diagnosis of T2DM, as found, for example, in the Munich General Practitioner Project. Some 40% of patients showed CHD-related ECG changes. The reasons for this observation seem to be complex and include, for example, a potential long lag time between the clinical onset and diagnosis of T2DM or clustering of other CV risk factors such as hypertension or dyslipidemia with T2DM—also seen in the Munich GP Project [5]. This latter phenomenon is often referred to as the metabolic syndrome and originates in the dysglycemic diabetic pre-state below the threshold of T2DM. Epidemiologic evaluations have shown that the risk for CV events is several

fold increased up to 15 years prior to the diagnosis of diabetes. Furthermore, when oral glucose tolerance tests have been applied, the state of glucose intolerance and—to a lesser degree—the state of impaired fasting glucose were found to be associated and highly predictive not only for CV events and mortality, but also all-cause mortality [6,7]. The association with fasting glucose may even show a J-type curve in that very low glucose concentrations at the far low end are also associated with increased all-cause and CV mortality [8]. Very low fasting glucose, however, may not necessarily be a causative factor for CV mortality, but may rather be a surrogate of high CV risk as associated with confounding comorbidities and diseases.

Duration of diabetes and CHD

Notwithstanding the fact that CHD may be present at diagnosis of T2DM, there is also an excessive rise of CV events and mortality with duration of diabetes, both type 1 and 2, in comparison to age-matched nondiabetic cohorts [9]. Looking into gender differences, the relative risk of women with diabetes for CVD as compared to women without diabetes is significantly higher than in diabetic versus nondiabetic men [9]. In longitudinal studies starting around 1990, after some 20 years of diabetes, about 40–50% of patients of both types and sexes have died from CV causes, in contrast to only about 7% of women and 16% of men without diabetes [1]. On the other hand, since the 1970s a secular trend for a reduction of CV and CHD mortality by about 70% has also occurred in people with diabetes, probably due to the progress in CV risk factor management and interventional cardiology [2]. Diabetes today is no longer an equivalent of CHD (i.e., a 10-year CV mortality risk of more than 20%, as stated in the 1990s based on cohorts studied in the 1980s). In fact, the CV mortality risk depends largely on coexisting CV risk factors and seems to be down well below 10% over 10 years on average in contemporary cohorts [10]. However, diabetes still carries a twofold elevated CV mortality risk compared to nondiabetic subjects.

Acute coronary syndromes and diabetes

The enormous interaction of diabetes and CHD is exquisitely visible at the interface of acute coronary syndromes (ACS) and hyperglycemia/diabetes. Random blood glucose concentration on admission with ACS is highly predictive not only for in-hospital mortality, but also for the prognosis longer term: the higher the level, the poorer the outcome. The striking prevalence (a total of 70–75%) of coexisting known diabetes, previously undiagnosed overt diabetes, and prediabetes in patients with ACS and CHD has already been mentioned. Both the Euro Heart Survey on Diabetes and the Heart, and the German SWEETHEART Registry have looked into this in some detail [3,11]. The poorest prognosis in terms of mortality and MACCE (major adverse cardio- and cerebrovascular events, i.e., deaths and nonfatal MIs and strokes) over the subsequent years is seen in those ACS patients with known diabetes, followed by those with new diabetes; with a trend for a poorer outcome in

those with prediabetes emerging at 3-year follow-up compared to nondiabetic controls. A similar "dose–effect" of known, new, and prediabetes has also been observed in the context of PCI (percutaneous coronary intervention). Treating newly diagnosed diabetes in ACS patients appeared to be beneficial in observational studies longer term, for example in the Euro Heart Survey at 1-year follow-up [12], whereas the benefit of an acute attempt to normalize glycemia on admission with ACS has remained controversial after studies like DIGAMI 1 and 2, CREATE-ECLA, and others. It seems reasonable to target a blood glucose concentration of about $150 \, \text{mg} \, \text{dL}^{-1}$ in an acute situation, if necessary with insulin, but to avoid any degree of hypoglycemia. The latter seems to signal a bad prognosis, also in those without diabetes and insulin. It is hoped that once blood glucose-lowering drug therapies without risk of hypoglycemia, for example incretin-based therapies, have been approved for use in ACS, more robust recommendations for dealing with hyperglycemia in ACS will become available.

Prognosis of CHD and diabetes

The prognosis of CHD in diabetes largely depends on coexisting CV risk factors and additional confounding conditions such as more severe impaired kidney function, cardio-neuropathy, complicating heart failure, severe lung or liver dysfunction, inflammatory disease, and frailty of any origin [10]. As already touched upon, however, the extent of hyperglycemia—best measured as HbA1c—was also found to be highly predictive for macrovascular, especially cardiac fatal and nonfatal events in numerous long-term observational studies. A 1% increase of HbA1c seems to be associated with an 18% increase of incident CV complications. In the Munich GP Project looking at mortality over 10 years, the association with initial HbA1c concentration was also confirmed in the subgroup that were already diagnosed at baseline as having significant macrovascular disease [13]. Based on epidemiologic judgment, including the observational data from recent large-scale trials such as ACCORD [14] and ADVANCE [15], an attained mean HbA1c level of 7% and less is seen as helpful to minimize macrovascular events, provided those levels can be achieved safely and without hypoglycemic episodes.

Hypoglycemia has emerged as an important factor, in the context of cardiovascular mortality, which complicates blood glucose-lowering therapy (see also later in this chapter). In three of the recent randomized and controlled intervention trials (RCTs) evaluating more intensive blood glucose-lowering treatment, hypoglycemic events were a strong predictor of CV mortality. This does not necessarily mean causality, but may indicate a high CV risk situation due to other coexisting disease. At any rate, hypoglycemia was felt to play a major role in why more intensive blood glucose-lowering therapy yielded only mixed CV outcome results in RCTs, for example in ACCORD [14], ADVANCE [15], and VADT [16]. It seems noteworthy in this context that severe hypoglycemia also occurred in the less intensively treated group and in association with increased CV

mortality, whereas the intensive treatment group, especially those patients with the highest updated HbA1c levels, showed the highest mortality risk. In the UKPDS, the beneficial effect of more intensive therapy in reducing myocardial infarction was of borderline significance after 10 years of this RCT, and only became significant after 10 years' further observation as a "legacy effect" [17]. Similarly, DCCT (a trial in T1DM) produced a legacy effect in terms of preventing CV events during the open observation period after the end of the RCT [18]. ORIGIN, which besides overt T2DM included also newly diagnosed diabetes and prediabetic subjects at high CV risk or with coexisting CVD (some 60% of participants), generated only an HbA1c difference of 0.3% over time, and did not demonstrate a more favorable CV outcome in patients with more intensive glycemic control [19]. Conversely, several meta-analyses based on UKPDS, ACCORD, ADVANCE, and VADT showed a significant reduction of nonfatal myocardial infarction and of all cardiac events of some 15–17% associated with a mean HbA1c reduction of 0.9% over a mean follow-up time of 5 years [20]. Looking at the subgroup with pre-existing macrovascular disease, however, no benefit of more intensive blood glucose-lowering treatment could be substantiated in these meta-analyses.

So, in aggregate, especially in patients with coexisting CVD, an individualized, patient-centered blood glucose-lowering approach is warranted. Care should be taken, not to do harm, and when addressing HbA1c lowering, always start slow, do not be overaggressive, go slow. An HbA1c of 7% or even lower may be fine, as long as there are no discernible side effects. In case of a baseline HbA1c above 8%, a reduction below 8% seems to be a reasonable first step (as a safeguard to prevent more severe microvascular disease). Further HbA1c reduction should be advised *only* if it can be done safely, that is, without inducing hypoglycemia.

To achieve HbA1c goals, recommendations for glycemic targets are also needed. The ORIGIN study has shown that targeting fasting plasma glucose concentrations of 95 mg dL^{-1} is safe and associated with only a low rate of severe hypoglycemia in about 1/100 patient-years. As to postprandial glucose levels and their predictive impact of increasing CV complications in long-term studies, a target glucose concentration of 180 mg dL^{-1} two hours after a meal seems to be a reasonable goal and should ensure an HbA1c result of about 7%. Key characteristics of the five studies evaluating intensification of blood glucose-lowering therapy are summarized in Table 73.1.

Screening for diabetes and prediabetes in patients with established CHD

Three good reasons seem to underpin the recommendation to screen for diabetes and prediabetes in patients with established CHD: (1) the high prevalence of undiagnosed diabetes and prediabetes in patients with both chronic and acute CHD; (2) the associated adverse impact of these conditions on the further prognosis; (3) the potential of improving the prognosis by appropriate therapeutic measures. As surveys such as the Euro Heart Survey and the SWEETHEART Registry of the Silent Diabetes Study have shown, performing an oral glucose tolerance test has remained the assessment of choice to diagnose these hidden metabolic disorders, notwithstanding the fact that well-standardized HbA1c measurements have been approved for the diagnosis of diabetes [3,21]. Both measurements of fasting plasma glucose and HbA1c, however, have been found to miss the diagnosis of two-thirds of all cases with overt diabetes as detected by an oral glucose tolerance test (OGTT) [3,21]. Furthermore, impaired glucose tolerance can only be detected by an OGTT per definition.

In practical terms, it seems useful to arrange for an examination of the glycemic status in all patients with established CHD, unless diabetes is already known. This can be done in the context of coronary angiography or other imaging procedures of the heart for patients with chronic CHD, and for patients with ACS at the end of their stay in the Coronary Care Unit and after stabilization of the patient's circulation. To minimize the

Table 73.2 Screening for diabetes in all patients with acute or chronic CVD and without known diabetes

- Step 1: random plasma glucose on hospital admission or fasting plasma glucose on elective consultation in combination with measurement of HbA1c
- If values are below the diagnostic threshold for overt diabetes (i.e., HbA1c <6.5 %, fasting plasma glucose <7.0 mmol/l or 126 mg dL^{-1}, random plasma glucose <11.1 mmol/l or 200 mg dL^{-1}), step 2 is mandatory
- Step 2: oral glucose tolerance test with 75 g glucose and measurement of fasting and 2-hour post load glucose, provided circulatory conditions of the patient are stabilized
- Every new diagnosis of diabetes needs confirmation at an independent, second time point

need to perform an OGTT, it has been suggested to do a combined measurement of fasting plasma glucose and HbA1c first, subsequently followed by an OGTT in cases where readings under the cut-off for overt diabetes were obtained in the first instance (see also Table 73.2).

Specific clinical features of CHD in diabetes

Morphology of CHD
In patients with diabetes, accelerated coronary artery disease is common. In adult diabetic patients, a three- to fourfold prevalence of CHD as compared to the general population has been observed. In patients with diabetes, a diffuse and rapidly progressive form of atherosclerosis is common [22]. Furthermore, a higher incidence of two- and three-vessel disease has been reported [23]. Based on imaging methods such as ultrafast computed tomography or intravascular ultrasound, a greater extent of calcification and a decrease in adaptive remodeling of atheroma have been detected. In addition, an increase in macrophage infiltration, vasoconstriction, adhesion molecule activation, inflammation, coagulation, and platelet activation has been reported. In patients with diabetes, a more pronounced plaque burden and positive remodeling have been found [24]. A study based on multislice computed tomography, found a higher prevalence of obstructive atherosclerosis in patients with T2DM as compared to patients with T1DM. In addition, noncalcified plaques were more common in patients with T2 than with T1DM [25].

Symptomatology
Angina pectoris, dyspnea, nausea, fatigue, and light-headedness are reported as typical symptoms of cardiac disease. Due to diabetic autonomic dysfunction, symptoms may not be characteristic or may be either partially or entirely absent. Shortness of breath, sweating, or profound fatigue are often recorded complaints [4].

In the recently published "Silent Diabetes Study," a significant correlation between the prevalence of abnormal glucose regulation (impaired glucose tolerance, diabetes) as detected by OGTT and the extent of CAD has been detected [21]. The study also

ties in with a prevalence of undetected diabetes of more than 20% in patients with acute myocardial infarction, which has also been found by different studies. It has been demonstrated that glucose metabolism is altered in a large proportion of patients with acute myocardial infarction and no previous diagnosis of diabetes mellitus [21].

Cardiac autonomic neuropathy
Cardiac autonomic neuropathy (CAN) is one of the most common complications associated with diabetes. It is caused by injury to the autonomic nerve fibers that innervate the heart and blood vessels. An increased risk of mortality and major cardiovascular events has been reported to be associated with CAN [4]. Different pathogenic mechanisms are considered [26].

- Activation of the polyol pathway, which is followed by an accumulation of sorbitol and fructose, a depletion of myoinositol, and a reduction of Na+/K+-ATPase. In this way, intracellular osmotic stress is increased.
- Accumulation of non-esterified free fatty acids and advanced glycation end-products (AGEs) as a result of hyperglycemia. The expression and production of vasoconstricting factors such as endothelin-1 and angiotensin increases, while the generation of vasodilatating agents such as prostacyclin (PGI2), substance P, calcitonin gene-related peptide (CGRP), endothelium-derived hyperpolarizing factor, and bradykinin decreases. Thus, microvascular damage arises.
- The expression of different isoenzymes of proteinkinase C (PKC) is altered by hyperglycemia-induced intracellular oxidative stress. Therefore, NO-dependent vasodilatation is inhibited, and expression of cytokines is enhanced. Both contribute to endothelial dysfunction.
- Activation of mitogen-activated protein (MAP) kinases, which contribute to a range of fundamental cellular processes such as growth, proliferation, and differentiation.
- Reduced circulation, followed by endoneural and ganglionar hypoxia, which is accompanied by myocardial hypoxia.
- Lack of neuronal growth factors and impairment of axonal re-transport.
- Autoimmune reactions against sympathetic nervous tissue (only T1DM) are linked with cardiac autonomic nerval function.

The functional and structural performance of the myocardium is strongly dependent on the balance between sympathetic and parasympathetic neural function. Exercise intolerance, orthostatic intolerance, and syncopies have been reported as typical symptoms associated with CAN. Since these symptoms usually occur late in the disease process, they are only weakly related to symptom scores in mild CAN.

Due to good sensitivity, specificity, and reproducibility, cardiovascular reflex tests are considered as the gold standard in clinical autonomic testing [27]. In patients with proliferative retinopathy a Valsalva maneuver may not be performed due to the risk of vitreous hemorrhage [27]. Heart rate variability (HRV) testing with deep breathing is the most widely used

assessment of cardiac autonomic function and has about 80% specificity [27].

ECG-based functional tests, however, have the disadvantage, that early stages of cardiac autonomic dysfunction often remain undetected. The heterogeneity of cardiac dysfunction, predominance of posterior wall region, and the extent of cardiac sympathetic dysfunction have been widely unknown up to the introduction of quantitative scintigraphic assessment of sympathetic innervation via techniques such as SPECT and PET [28].

Scintigraphically assessed cardiac sympathetic dysinnervation is frequently observed in type 2 diabetic patients. The pattern of cardiac sympathetic dysinnervation is heterogeneous, whereas the posterior myocardium is predominantly affected. Type 2 diabetic patients with ECG-based cardiac autonomic neuropathy demonstrate a more pronounced dysinnervation of the posterior myocardial region than type 2 diabetic patients without. In the patients, the posterior myocardial I-123-MIBG uptake is associated with heart rate variation at rest and during deep breathing and heart rate response to standing [29]. Furthermore, global, anterior and apical I-123-MIBG uptake is related to heart rate variation at rest and during deep breathing.

The high degree of reduced I-123-MIBG uptake in type 2 diabetic patients without ECG-based cardiac autonomic neuropathy emphasizes the view that cardiac sympathetic dysinnervation is observed before ECG-based cardiac autonomic neuropathy is diagnosed. Potential differences in uptake of I-123-MIBG between T1 and T2DM are not yet fully understood and may also be related to differences in pathophysiology between the types of diabetes.

In general, CAN is suggested to be composed of a reversible metabolic component and an irreversible structural component [30]. With increase in duration of diabetes, the reversible component is considered to decrease while the irreversible component augments, respectively [30].

Studies that did not scintigraphically exclude myocardial perfusion defects reported a substantial reduction of cardiac I-123-MIBG uptake in type 2 diabetic patients [31]. A comparative investigation of I-123-MIBG uptake with power spectral analysis of heart rate variability in T2DM observed a relationship between I-123-MIBG uptake and parameters of power spectral analysis. In type 2 diabetic patients with silent myocardial ischemia, diffuse abnormalities of I-123-MIBG uptake have been demonstrated.

The predominant affection of the posterior myocardium of type 2 diabetic patients points at a particular vulnerability of the posterior cardiac sympathetic nervous system. A comparable heterogeneous pattern of cardiac sympathetic dysinnervation has been observed in arrhythmogenic right ventricular cardiomyopathy and in patients with ventricular arrhythmias in the absence of coronary artery disease. Therefore, the regional imbalance of cardiac sympathetic innervation in T2DM may enhance the potential for arrhythmogenicity.

In type 2 diabetic patients, heart rate variation is significantly associated with global and regional distributions of myocardial uptake of I-123-MIBG. Investigation of 24-h heart rate variability demonstrated a relationship with I-123-MIBG uptake in type 2 diabetic patients without evidence for coronary artery disease. Cardiac reflex tests assessing heart rate variation have been suggested to mainly reflect cardiac parasympathetic function.

Tests reflecting mainly cardiac sympathetic function such as Valsalva maneuver and systolic blood pressure response neither correlated with global nor with regional I-123-MIBG uptake. Applying power spectral analysis of heart rate variability, evidence for a relationship between low-frequency components, which is believed to mainly reflect sympathetic function, and I-123-MIBG uptake has been reported in T2DM. Comparisons with scintigraphically assessed sympathetic function support the view that the tests on heart variation do not absolutely differentiate between sympathetic and parasympathetic function.

Cardiomyopathy

Diabetic cardiomyopathy may develop independently of elevated blood pressure or coronary artery disease. This complex diabetes-associated complication is characterized by a range of molecular, structural, and functional changes (Table 73.3 [32]).

The healthy heart is able to metabolize various substrates such as free fatty acids (FA), glucose, lactate, pyruvate, ketone bodies, and amino acids. Under normal resting conditions, cardiac metabolism is mainly oxidative, and 60–90% of the ATP arise from ADP oxidative phosphorylation and fatty acid oxidation. Under stress conditions, such as ischemia or hypertrophy, oxidation of FA is decreased and exogenous glucose is mainly utilized [33,34]. The healthy heart is able to switch rapidly between different energy sources to adjust to different requirements.

As an aerobic organ, the heart is relying to a large extent on the aerobic oxidation of substrates. The myocardial oxygen consumption is closely linked to the main determinants of systolic function, namely, heart rate, contractile state, and wall stress. In pathologic states such as heart failure or cardiomyopathy, mechanical efficiency (ratio of produced useful energy to consumed oxygen) is reduced.

Due to profusion of triglycerides and non-esterified FA, the diabetic heart essentially relies on FA oxidation, despite the presence of hyperglycemia and even during myocardial ischemia. Regardless of enhanced FA utilization, FA uptake is assumed to overcharge the oxidation capacity, resulting in myocardial lipid accumulation that may promote lipotoxicity. The latter causes impaired beta-oxidation, thus generating even more free FA. Hence, an intrasarcoplasmic excess of neutral lipids and their intermediates is originated, and directed to signaling pathways whose hyperactivity then affects ATP production, insulin sensitivity, cell contractility, and apoptosis, all contributing to diabetic cardiomyopathy.

The levels of intracellular FA derivatives like fatty acyl-coenzyme A (CoA), diacylglycerol and ceramide increase with augmenting intracellular fatty acid amounts. Fatty acyl-CoA species are able to inhibit glycolysis and are presumed to regulate

Phase	Molecular and cellular events	Structural and morphological alterations	Myocardial capacity
1	• Metabolic: hyperglycemia, increased circulating FFA, insulin resistance • Altered Ca2+ homeostasis • Endothelial dysfunction	• Insignificant changes: normal LV dimensions, wall thickness, and mass.	• Impaired diastolic compliance with normal systolic function, or no obvious functional changes.
2	• Cardiomyocyte injury, apoptosis, necrosis • Activation of cardiac fibroblasts (myocardial fibrosis)	• Minor changes: slightly increased heart mass, wall thickness or size. • Cardiomyocyte hypertrophy. • Insignificant myocardial vascular changes.	• Significant changes in diastolic and systolic function.
3	• Hypertension • CAD • Microangiopathy • CAN	• Significant changes: increased heart size, wall thickness and mass. • Myocardial microvascular disease.	• Abnormal diastolic and systolic function.

FFA, free fatty acids; CAD, coronary artery disease; CAN, cardiac autonomic neuropathy; LV, left ventricular.

glucose uptake. Diacylglycerol activates distinct isoforms of protein kinase C, thereby eliciting insulin resistance.

Activation of these protein kinase C isoforms is assumed to be linked to glucose spikes and glucose excess with early changes of sympathetic incompetence, impaired NO release and endothelial dysfunction and activation, ultimately leading to severe damage, such as heart failure, plaque instability, arterial thrombus formation, and death.

Beyond increased FA levels, the mechanisms contributing to substrate switching in diabetic hearts include decreased insulin signaling, and activation of transcriptional pathways such as the peroxisome proliferator-activated receptor-α (PPARα)/PGC-1 signaling network that regulates myocardial substrate use. Accordingly, activation of PPARα stimulates the formation of pyruvate dehydrogenase (PDH) kinase 4, which attenuates glucose oxidation by decreasing PDH activity.

Moreover, PPARα stimulates the activation of genes such as CD36, regulating cellular FA uptake, and malonyl CoA decarboxylase, degrading malonyl CoA, thereby depressing carnitine palmitoyl transferase-1 and stimulating mitochondrial FA uptake. Further transcriptional targets of PPARα are medium- and long-chain acyl CoA dehydrogenase and hydroxyl acyl CoA dehydrogenase, both involved in beta-oxidation [35].

PPARα is highly expressed in tissues deriving most energy from FA oxidation, including liver, heart, kidney, and skeletal muscle. PPARα target genes are involved in lipid metabolism, for instance the genes of heart-type FA-binding protein (hFABP), lipoprotein lipase (LPL), CD36, carnitine palmitoyltransferase-1 (CPT-1), and uncoupling protein-3 (UCP-3). Cardiac PPARα excess enhances FA uptake and oxidation.

Increased FA metabolism not only leads to accumulation of FA and triglycerides, but also stimulates oxygen consumption and formation of reactive oxygen species (ROS). Excessive FA uptake through overexpression of LPL or FA transporters, or by stimulating PPARα expression or long-chain CoA synthase results in a cardiac phenotype equal to diabetic cardiomyopathy.

Beyond FA and lipotoxic aspects, the contribution of dysregulated carbohydrate metabolism and glucotoxicity to diabetic cardiomyopathy has to be considered. A significant reduction in myocardial glucose utilization has been demonstrated in isolated diabetic cardiomyocytes and in diabetic patients.

The slow rate of glucose transport across the sarcolemnal membrane into the myocardium as a limiting factor of cardiac glucose utilization is suggested to be caused by the cellular depletion of glucose transporters 1 and 4 (GLUT1 and GLUT4). Reduced myocardial GLUT4 content and a defect in GLUT4 translocation are the earliest changes being observed in short-term studies of mice under a high-fat diet, causing reduced rates of glycolysis and glucose oxidation.

According to the Randle hypothesis, glucose accumulates in the cells and is deflected to alternate metabolic pathways, especially the pentose phosphate pathway and the hexosamine biosynthetic pathway. Among others, increased intracellular levels of UDP-N-acetylglucosamine are suspected to alter excitation/contraction coupling by activating the O-linked glycosylation of target proteins.

Oxidative stress plays a key role in the pathophysiology of diabetic cardiomyopathy. According to recent studies, the maladaptation of the heart is based on metabolic dysfunction associated with diabetes. Key factors contributing to oxidative stress in diabetic patients in particular are [34–37]

- excess formation of ROS induced by hyperglycemia, AGE, and elevated free FA;
- reduction of antioxidant defense;
- increase in mitochondrial ROS generation;
- ROS-mediated activation of factors that are involved in the pathogenesis of diabetic cardiomyopathy: inflammation, endothelial dysfunction, cell death, cardiovascular remodeling;

- activation of transcription factors, polyol and hexosamine pathways, tyrosine kinase pathways.

Heart failure

Type 2 diabetes and poor glycemic control have been identified as common factors influencing the incidence of heart failure. In people with diabetes, a significantly increased risk of heart failure has been demonstrated [38]. Additionally, annual mortality of diabetic patients with heart failure is increased by more than 10-fold as compared with diabetic patients without heart failure [38].

Echocardiography has been established as the preferred method for documentation of cardiac dysfunction. The left ventricular (LV) ejection fraction (EF) is the most important measurement for the assessment of impaired systolic function. In patients with normal or mildly abnormal LV systolic function, abnormal LV relaxation, diastolic distensibility, or diastolic stiffness are echocardiographic signs of diastolic dysfunction. Echocardiography, including tissue Doppler imaging is useful in detecting myocardial dysfunction in diabetic patients, as well as in nondiabetics [4].

Measurement of plasma concentrations of natriuretic peptides or their precursors for diagnosing heart failure may also be helpful in patients with diabetes.

Diastolic dysfunction is a well-established abnormality in diabetes mellitus, probably in the context of hypertension and perhaps cardiomyopathy leading to a disordered filling of the left ventricle. Quantitative and qualitative changes of the extracellular matrix formation of the heart have been observed dependent upon hyperglycemia and an excess of glucose in animal and *in vitro* studies and may play a role also in the human situation [28].

Echocardiographic investigations show a rapid improvement of heart muscle performance with stimulating glucose uptake by insulin administration in diabetic patients with ischemic heart disease. On the contrary, abundant concentrations of free FA may weaken cardiac pump function and, in addition, induce severe arrhythmias.

Blood flow and in particular reactive hyperemia induced by hypoxia may be impaired even in the absence of advanced atherosclerosis in view of profound endothelial dysfunction, and also activation, both of which seem to occur quite early on in diabetes [28].

Microvascular disease of the heart

Microangiopathy represents a common and widespread manifestation in patients with multiorgan involvement. Abnormalities of coronary microcirculation have been reported in clinical diabetes mellitus using invasive or noninvasive procedures. Noninvasive studies using positron emission tomography (PET) with N-13 ammonia demonstrated a largely unaltered maximal endothelial-independent myocardial vasodilatory capacity induced by adenosine or dipyridamole stress testing and an impaired response to sympathetic mediated stimulation by cold pressor test (CPT) in diabetic patients, which assessed endothelial-dependent blood flow [39].

Dysregulation of coronary vascular function in response to CPT was found to be present in approximately one third of those diabetic patients without clinical signs of coronary artery disease [39]. Diabetic patients presented with higher baseline myocardial blood flow (MBF) at resting conditions and a paradoxical coronary vasoconstriction during the CPT [39]. Scintigraphic assessment, therefore, demonstrates complex patterns of dysregulation of myocardial blood flow in diabetes, which is even present in the absence of coronary artery disease.

Arrhythmias

Due to reduced cardiac ejection fraction and systolic dysfunction, impaired sympathetic and parasympathetic responses, and decreased diastolic filling, CAN is associated with a reduction in exercise tolerance [40]. An imbalance between right and left sympathetic innervation is reported to correspond with a prolonged corrected QT interval and QT dispersion (the difference between the longest and shortest QT interval) [40]. Diabetic patients with a regional sympathetic imbalance and QT interval prolongation are suggested to be at higher risk for arrhythmias [40]. Hypoglycemia has been found to contribute significantly to increased risk of arrhythmias (see earlier and following section).

Cardiovascular risk related to diabetes therapy

Defining the vulnerable patient with critical hypoglycemia

Data from long-term controlled interventional trials with intensified glycemic control such as the DCCT for T1DM [41] and the UKPDS for newly diagnosed T2DM [42] have shown fewer cardiovascular events with better glucose control. Similarly, the incidence of major cardiovascular events was reduced by 17% with more intensive diabetes control in a recently published meta-analysis of five mega-trials; however, no effect was seen for all-cause mortality or stroke [20]. Intensified glucose control with basal insulin glargine in the ORIGIN trial, however, had no effect on any cardiovascular event rate compared to standard care with metformin and sulfonylureas when necessary, despite a sustained maintenance of HbA1c <6.5% [19]. In all these studies (see also Table 73.1) intensified glucose-lowering treatment was associated with an increase in hypoglycemic episodes. Furthermore, severe hypoglycemia, defined as any episode that requires external assistance, was associated with an increased mortality rate in all these studies [43]. In the DIGAMI 2 study involving patients with acute coronary syndrome, long-term insulin treatment was associated with significantly higher mortality compared to active comparator metformin; this notion seems to point to the fact that a strategy of antidiabetic treatment with higher risk of hypoglycemia may trigger cardiovascular complications [44]. However, in patients hospitalized with acute myocardial infarction, iatrogenic hypoglycemia after

insulin therapy was not associated with increased mortality [45]. Further of note, mild hypoglycemia, for example self-reported and self-treated episodes, was not associated with a significant increase in mortality in a large retrospective trial using the Charlson comorbidity index to minimize selection bias by the decision of more intensive glucose-lowering treatment [46]. In a large retrospective registry study with 845 type 2 diabetes patients, 3.1% reported a hypoglycemic event. The odds ratio for acute cardiovascular events for those with hypoglycemia was 1.79 [47]. So far, little is known about the contribution of harmful cardiovascular effects of hypoglycemic episodes such as incident arrhythmias, ischemic reactions, and increased cardiac work load on major CV events and mortality. Investigations with continuous glucose measurement systems (CGMS) show a close relationship between episodes of critical low glucose levels (below $3.1\,\mathrm{mmol\,L^{-1}}$) and ventricular arrhythmias as well as ischemic changes in parallel ECG recording [48,49]. Rapid glycemic fluctuations produce oxidative stress [50] with potential harmful effects on electric stability of the heart. Thus, impaired glucose homeostasis could precipitate major CV events in a multistage metabolic and hormonal stress reaction leading to electric instability and ischemic reactions in patients with acute coronary syndrome or multivessel disease [51].

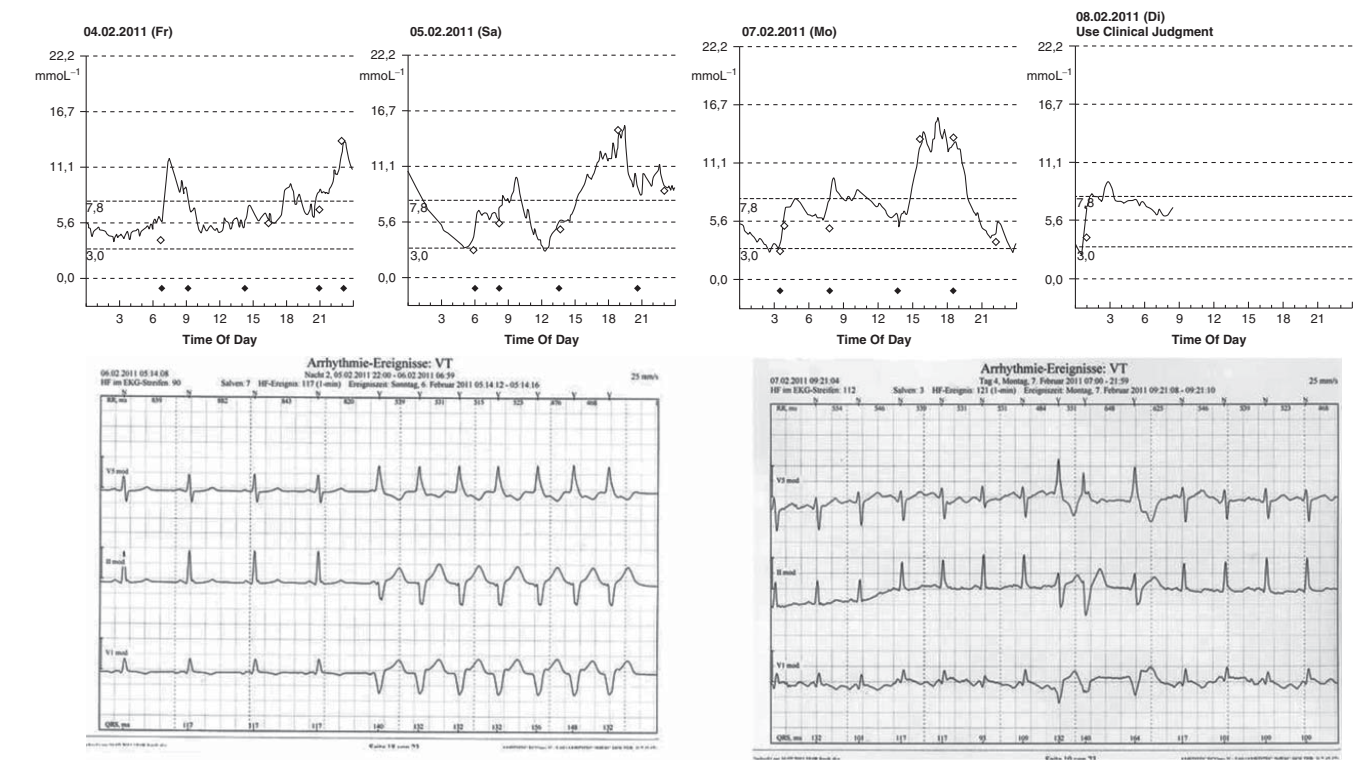
Mechanisms and links to cardiovascular complications during critically low glycemia

Sudden death in patients with T1DM without coronary heart disease observed during sleep has been described as "dead-in-bed" syndrome [52]. Parallel measurements with Holter ECG and CGMS revealed a close association of long-lasting severe hypoglycemia triggering prolongation of QTc time and ending up with fatal tachyarrhythmias [53]. However, dead-in-bed syndrome is rare in young adults with T1DM without CHD despite a high frequency of nocturnal hypoglycemia [54]. The link between severe long-lasting hypoglycemias and fatal ventricular arrhythmias, however, illustrates that hypoglycemia may trigger serious CV complications in frail type 2 patients.

Hypoglycemia has long been known to be associated with hemodynamic alterations such as increase in heart rate, ectopic heart beats, chest pain, and increase in systolic blood pressure as a consequence of activation of the sympatho-adrenal system. Physiologic responses are release of stress hormones, in particular catecholamines, ACTH/glucocorticoids, and glucagon to protect end-organs and increase gluconeogenesis. At critical low glucose levels, however, this leads to an increased workload of the heart, impairs endothelial function and may have harmful effects on electric stability in vulnerable patients with CHD [54]. Mechanistic studies applying iatrogenic hypoglycemia have shown that a cascade of sympatho-adrenal counterregulations starts to stabilize glucose supply to end-organs, in particular of the brain, at levels of plasma glucose $<3.9\,\mathrm{mmol\,L^{-1}}$ [51]. However in healthy subjects, long-lasting low glucose levels (below $\sim3\,\mathrm{mmol\,L^{-1}}$) cause life-threatening ECG changes with lengthening of the QT interval. This prolongation of cardiac

repolarization predisposes to cardiac arrhythmias. Stress hormones such as catecholamines also lower serum potassium, a key player for electrophysiologic stability, which may further increase risk of arrhythmias [55]. By using radionuclide ventriculography it could be shown that hemodynamic changes due to insulin-induced hypoglycemia produced a sustained effect also on cardiac contractility which may be explained by prolonged and impaired repolarization during diastole [56]. Besides these hormonal/metabolic effects, there are other secondary critical changes that may affect thrombus formation and plaque stability in patients with CHD: activation of platelets and coagulation and increase in inflammatory cytokines [57]. Another critical aspect associated with hypoglycemia is its effect on autonomic cardiovascular function. As proven by CLAMP-studies in healthy subjects, baro-reflex sensitivity and appropriate sympathetic-vagal response to hypotensive stress are attenuated subsequent to hypoglycemia [58].

Coincidence of hypoglycemia and arrhythmias

Atrial fibrillation (AF) is a frequent finding in patients with T2DM. In the Atherosclerosis Risk in Communities Study the hazard ratio for AF in patients with T2DM was 1.35. However, prediabetes and newly diagnosed diabetes was not associated with increased risk of AF compared to subjects without diabetes [59]. In multivariate analysis diabetes, HbA1c and poor glycemic control were independently related to the risk of incident AF. Atrial fibrillation is common in diabetic patients with acute myocardial infarction. In a Russian study of patients with myocardial infarction, 42.1% with T2DM had extra-systolic beats and AF versus 30.4% without diabetes. Cardiac arrhythmias were directly correlated with coronary and myocardial dysfunction and were prognostically unfavorable factors for survival rate [60]. Furthermore, in patients with heart failure rapid changes in glucose levels measured with CGMS as mean amplitude of glucose excursions (MAGE) were associated with serious arrhythmias at MAGE $>5\,\mathrm{mmol\,L^{-1}}$. As a consequence, a significant increase in cardiac mortality was observed in this very high-risk population [61]. No benefit of aggressive glucose control could be observed in patients with diabetes undergoing coronary artery bypass graft surgery because of a higher incidence of hypoglycemic episodes with harmful effects on cardiac work load and electric stability [62]. Parallel recording of CGMS and ECG in vulnerable patients with advanced T2DM and CVD treated with insulin or/and sulfonylurea reveals a high incidence of asymptomatic nocturnal episodes of severe hypoglycemia associated with silent ventricular tachycardias (Figure 73.1)[63]. Cardiac autonomic neuropathy has been identified to be associated with an excessive mortality ([64], see also earlier in this chapter). It aggravates risk of ventricular tachycardia in the case of hypoglycemia [65]. By extrapolation of these data in accordance with the anecdotal finding of dead-in-bed syndrome in T1DM, it may be suggested that severe hypoglycemia via arrhythmias and coronary ischemia fuels a vicious cycle which may cause


Male, 56 years, BMI 43.3, HbA1c 6.9%, previous apoplexia
Therapy: Metformin 2000 mg, Detemir 60 IU, Humalog 70 IU

Figure 73.1 High fluctuations are associated with arrhythmias.

sudden death by ventricular fibrillation or heart failure in frail patients. However, there is no evidence at present for causality between overall hypoglycemia and cardiovascular events. Outside of cardiovascular clinics with continuous monitoring of ECG and glucose levels only a few studies with 2–5 days of ECG recordings exist. Thus, the contribution of arrhythmias induced by hypoglycemia to an adverse outcome in patients with CVD or with heart failure under real-world conditions is uncertain.

Impact of antidiabetic treatment on risk of hypoglycemia and arrhythmias

The risk of cardiovascular events associated with hypoglycemia related to antidiabetic drugs has been a matter of controversial debate for a long time. Only scarce data is available for insulin and sulfonylureas. Both classes of drugs can cause long-lasting hypoglycemia and rapid glucose fluctuations with possible effects on myocardial blood flow and electric stability. In the UKPDS legacy analysis, intensified treatment with sulfonylurea and/or insulin was associated with significantly lower cardiovascular event rate and all-cause mortality compared to conventional therapy, despite a higher rate of hypoglycemic episodes during the intervention phase with those classes of drugs [66]. In the ADVANCE study, intensified treatment with the sulfonylurea gliclazide was associated with increased risk of hypoglycemia, but no association between hypoglycemia and cardiovascular mortality was observed [43]. Mechanistic studies, however, suggest that sulfonylurea drugs may have harmful effects on myocardial ischemia tolerance and electric stability in patients with acute coronary syndrome. In a comparative trial of patients with acute myocardial infarction undergoing angioplasty in-hospital mortality was significantly higher in patients treated with sulfonylurea (OR 2.77). Sulfonylurea intake at time of acute myocardial infarction, however, was not related to late outcome [67]. In a CLAMP study, heart rate variability in response to hypoglycemia was impaired in patients with T2DM after a single dose of glibenclamide in the morning, resulting in a higher risk for critical arrhythmias during hypoglycemic episodes [68]. Strict glucose control with basal insulin glargine versus standard care in the ORIGIN trial was associated with a significantly higher incidence of severe hypoglycemic episode (1.0% vs. 0.3% per year), but cardiovascular outcome was neutral and only one death may have been related to hypoglycemia [19]. Thus, data derived from DIGAMI 2 [44] and the European Heart Survey [69] suggesting a higher risk with insulin treatment could not be confirmed. Furthermore, a large retrospective cohort of patients hospitalized with acute myocardial infarction in 40 hospitals in the US was evaluated for the relationship between spontaneous and insulin-induced hypoglycemia and mortality. Iatrogenic hypoglycemia after insulin treatment was not associated with higher mortality, while spontaneous hypoglycemia showed an increased OR for mortality of 2.32 [45]. This puzzling finding may be explained by the fact that insulin counteracts oxidative stress due to rapid glycemic fluctuations as shown in CGMS-based cohort investigations [70].

By extrapolation so far, there is no definite evidence for additional harmful effects of insulin or sulfonylureas in the context of hypoglycemic episodes in long-term studies. In acute coronary syndrome sulfonylurea may deteriorate tolerance to ischemia.

Conclusion

Review from the literature, mechanistic studies and clinical experience in patients with CHD and heart failure suggest that severe hypoglycemia and rapid glucose fluctuations can initiate a cascade of pro-arrhythmic and ischemic reactions which may lead to fatal cardiovascular events or critical deterioration of heart failure. Pre-existing CHD and autonomic neuropathy label vulnerable patients. Antidiabetic drugs are the most common cause of hypoglycemia. No specific effects of glucose-lowering drugs on risk of hypoglycemia are known so far. While we have only proof for causality from in-hospital patients with acute coronary syndrome and some anecdotal cases with dead-in-bed syndrome, intensive glucose-lowering therapy in frail and elderly patients that could provoke critical low glucose levels and rapid fluctuations should be avoided.

Management aspects

No clear evidence for routine screening, but for risk reduction

The Detection of Ischemia in Asymptomatic Diabetics (DIAD) study, a randomized controlled trial in which 1123 participants with T2DM and no symptoms of coronary artery disease (CAD) were randomly assigned to be screened with adenosine-stress radionuclide myocardial perfusion imaging (MPI) or not to be screened, aimed to assess whether routine screening for CAD identifies patients with T2DM as being at high cardiac risk and whether it affects their cardiac outcomes [71]. The incidence of cardiovascular events was low in this cohort and thus the DIAD study failed to prove the benefit of a generalized screening of patients with diabetes mellitus. However, the ADDITION trial in which new diagnosed diabetic patients with no previous cardiovascular event were included and followed for 14 months showed a downward shift in the distribution of modeled cardiovascular disease (CVD) risk over 14 months, using the UKPDS risk engine. Older individuals, males, and those with a larger waist circumference at baseline exhibited smaller risk reductions. Individuals prescribed a higher number of drugs over the follow-up period, and those who decreased their energy intake or reduced their weight, demonstrated larger reductions in the modeled risk. This study revealed a beneficial effect of metabolic screening and of early intervention, and demonstrates the power of individual risk scoring following diagnosis of diabetes by using the UKPDS risk score in terms of reduction of cardiovascular risk [72].

The diabetic patient after the cardiovascular event

Up to one quarter of patients referred for coronary revascularization present with diabetes mellitus [73,74]; of those one third are admitted with acute coronary syndromes (ACS), and more than one third of patients present with cardiogenic shock. Diabetic patients undergoing revascularization procedures show a higher prevalence of previous myocardial infarction, congestive heart failure and arterial hypertension compared to nondiabetic patients [75] and the clinical outcome is impaired. Coronary artery disease is more severe in diabetic than in nondiabetic patients, the prevalence of three-vessel disease is more than 50% [76]. Heart disease in patients with diabetes has to be regarded as a composite of hypoxia through ischemia and malnutrition through impaired myocardial metabolism.

Furthermore, diabetes is associated with higher rates of restenosis after PCI of each type (balloon angioplasty or implantation of bare metal and drug-eluting stent) and is regarded as an independent predictor of early stent thrombosis both in the bare metal (BMS) and drug-eluting stents (DES) [77]. DES are more effective than BMS in reducing the rate of repeat intervention and MACE, although they have shown similar rates of death and myocardial infarction [78,79]. Although medical treatment has improved significantly over recent years the long-term risk of death, myocardial infarction and repeat revascularization is nearly twice as high in diabetic than in nondiabetic patients undergoing PCI [80]; ACC/AHA [81] and EAC/EACTS [82] guidelines recommend coronary artery bypass grafting (CABG) rather than PCI for diabetic patients with stable angina and multivessel coronary disease.

Lessons learned from revascularization trials

The main finding of the Bypass Angioplasty Revascularization Investigation (BARI) trial performed around 17 years ago was that patients with diabetes and multivessel disease undergoing CABG had a better prognosis for survival than patients in whom balloon angioplasty has been performed [83]. As a result the National Heart, Lung, and Blood Institute issued a clinical alert and CABG was recommended as the preferred approach for revascularization in these patients [84,85].

BARI findings were subsequently underlined by several studies showing that more major adverse cardiovascular and cerebrovascular events in patients with diabetes and multivessel CAD occurred who underwent PCI than among those in whom CABG was performed [86]. Significant improvements in antiplatelet therapy with availability of highly potent drugs (ADP receptor agonists and glycoprotein IIb/IIIa antagonists) mainly contributed to the higher success rates for CABG in multivessel disease. In particular, the diabetic patient profits from post interventional treatment with ADP receptor agonists [87,88].

Even the comparison of CABG to drug-eluting stents performed in the Coronary Artery Revascularization in Diabetes (CARDia) study [89] or by analyzing the diabetic subgroup of the Synergy between PCI with TAXUS and Cardiac Surgery (SYNTAX) study clearly showed the benefit of CABG. The SYNTAX trial compared 1800 patients with symptomatic left main and/or three-vessel coronary artery disease (CAD) treated with drug-eluting stents versus coronary artery bypass graft surgery [90]. Major adverse cardiovascular and cerebrovascular events at 12 months were more often for patients with multivessel disease who underwent PCI with drug-eluting stents compared to CABG [89,90], an effect which was even more prominent in the long-term follow-up of the SYNTAX patients [91].

A subgroup analysis from the COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation) trial furthermore suggested that the addition of early PCI to optimal medical therapy did not reduce the rate of adverse events after a median follow-up of 4.6 years [92]. The COURAGE trial randomized 2287 patients with stable angina and CAD to PCI plus optimal medical therapy versus optimal medical therapy alone, with a primary endpoint of all-cause mortality and nonfatal myocardial infarction (MI) [93]. In all subgroups, the outcomes of death or MI were similar in patients who underwent PCI or those who did not. In BARI 2 Diabetes (BARI 2D) this estimation was confirmed for diabetic patients as well [94].

The Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial is the most recently published study on this topic [95]. CABG was analyzed for superiority to PCI with drug-eluting stents in the treatment of 1900 high-risk patients with a good distribution of SYNTAX score and diabetes (about as many patients with diabetes as in all previous trials combined) and multivessel coronary artery disease. Consistent with the BARI 2D trial, optimal medical therapy was prescribed throughout the follow-up. After long-term follow-up (median 3.8 years), 947 patients assigned to CABG showed significantly lower mortality rate (10.9% vs. 16.3%) and fewer myocardial infarctions (6.0% vs. 13.9%) than 953 patients assigned to undergo PCI. However, patients in the CABG group presented with significantly more strokes (5.2% vs. 2.4%), mostly because of strokes that occurred within 30 days after revascularization and thus the benefit of CABG was driven by reductions in rates of both myocardial infarction and death from any cause. Regarding the primary composite outcome of death from any cause (myocardial infarction or stroke over 5 years), the incidence was reduced in the CABG group by 7.9 percentage points (18.7% vs. 26.6%; $p = 0.005$), as compared to PCI [95]. Taken together the results from 13 trials in more than 4000 patients with diabetes reveal that mortality has been consistently reduced by CABG, as compared with PCI of each type [91].

The metabolic component

Regarding the metabolic component in the elective treatment of the vascular diabetic patient no clear evidence for a benefit of tight HbA1c adjustment (HbA1c <7.0%) is available.

However, a BMI of $\leq 30\,\mathrm{kg\,m^{-2}}$ turned out to be of advantage in terms of outcome, a fact which is known as obesity paradox [96]. The meta-analyses of prospective randomized clinical trials including ADVANCE, ACCORD, and VADT clearly point to the reduction of fatal and nonfatal infarction and the risk of coronary events with intensified glucose control in terms of prevention. For an optimized therapeutic result the individual patient and his comorbidities have to be taken into account. Regarding the most efficient therapy, side effects like hypoglycemia should be considered and avoided. A multifaceted therapeutic concept which includes lifestyle modification (smoking cessation, dietary concepts, and physical exercise) should be combined with antithrombotic, lipid lowering, antihypertensive, and blood glucose normalization strategies. Strong evidence for this concept with a number needed to treat (NNT) below 10 is based on the Steno-2 trial which took into account high-risk patients and showed significant reduction of morbidity and mortality in these patients [97,98]. In combination with commonly used risk scores like UKPDS or CARRISMA patients at risk can be properly evaluated and treated [99,100]. It becomes obvious that not one factor per se but many factors in concert determine the outcome of patients with diabetes and heart disease. This again points to the fact that diabetic heart disease is not only an ischemia-driven disease but is also characterized by a strong metabolic component [100,101].

Concluding remarks

Not only do the recent published studies prove the superiority of CABG over PCI in the treatment of multivessel disease but newer developments in surgical techniques, such as minimal invasive procedures and "off-pump" surgery, which decrease manipulation of the ascending aorta with the risk of atherosclerotic emboli and activation of the complement system, potentially leading to multiple organ dysfunction and/or damage, will give additional substance to the preference of CABG over PCI. This is of particular interest in diabetic patients with more extensive atherosclerosis and higher risk of perioperative infection.

Arterial hypertension in diabetes: etiology and treatment

Colleen Flynn and George Bakris

Department of Medicine, Section of Endocrinology, Diabetes and Metabolism and the ASH Comprehensive Hypertension Center, The University of Chicago, Chicago, IL, USA

> ## Key points
>
> - Hypertension is a polygenic disorder that commonly accompanies type 2 diabetes and contributes to decline in kidney function as well as cardiovascular risk.
> - Increased sympathetic tone is a key factor in driving elevations in blood pressure in patients with diabetes.
> - Endothelial dysfunction associated with salt sensitivity increases blood pressure variability and contributes to increased risk of stroke.
> - Factors early in diabetes that improve endothelial function and reduce insulin resistance such as exercise and weight loss are key to reducing the risk of blood pressure elevation.
> - Randomized clinical trials support blood pressure goals below 140/90 mmHg but not <130/80 mmHg for cardiovascular risk reduction.

Introduction

Hypertension, defined as a consistent systolic blood pressure above 140 mmHg or a diastolic blood pressure above 90 mmHg on two separate occasions measured using American Heart Association criteria [1], affects more than 72 million Americans and is one of most prevalent risk factors that contributes to development of cardiovascular disease and chronic kidney disease [2,3]. The prevalence of hypertension is estimated at about 30% of the adult population in developed countries and is predicted to increase by almost 60% in the next two decades [4]. Diabetes is a major risk factor for cardiovascular disease [2]. Cardiovascular morbidity and mortality is increased substantially in the presence of diabetes [2,5]. In the natural history of type 1 diabetes (T1DM), development of an elevated BP (i.e., >130/80 mmHg) is a major predictor of nephropathy and future decline in kidney function; this is especially true in

those with a progressive rise in blood pressure over time and especially in those with a family history of kidney disease [2,6]. In contrast, hypertension is already evident in most patients with T2DM at the time of diagnosis. The implications of hypertension on cardiovascular risk, however, are similar in both types of diabetes [2,7]. Mortality is increased 7.2-fold when hypertension is present in patients with diabetes [2].

The contributing factors in the pathogenesis of hypertension in diabetes are multifactorial. For many years, it has been recognized that hypertension is common to both obese subjects and those with T2DM [8]. Blood pressure elevations in both these groups may be, in part, due to the presence of insulin resistance and resultant hyperinsulinemia as well as increased salt sensitivity. Support for this proposal is evident from studies of behaviors that improve insulin action, such as weight loss and increased physical activity and the resultant reduction in blood pressure into the normal range [9–11]. Additionally studies that are more recent demonstrate blunting of vasodilator responses to known stimuli and reduced nitric oxide release; factors associated with increases in salt sensitivity, that is, both systolic and diastolic blood pressure increase by >5 mmHg more than someone given the same salt load of 400 mmol d^{-1} [12,13].

To understand the contribution of insulin resistance in the genesis of hypertension fully, one has to evaluate the effects of insulin resistance and hyperinsulinemia on factors that contribute to blood pressure elevation. Insulin resistance is a metabolic disorder that is manifested by a reduction in peripheral skeletal muscle utilization of glucose, fatty acid, and protein metabolism [14]. Hence, higher concentrations of insulin (hyperinsulinemia) are needed to achieve the same level of glucose utilization in these tissues. Hyperinsulinemia is also associated with a number of physiologic changes in cellular function. Hyperinsulinemia may also contribute to the genesis of hypertension through its effects on sodium homeostasis and the sympathetic nervous system. Lastly, the effect of insulin

on various growth factors contributes to the development of vascular injury through its potentiation of the atherosclerotic process [15].

As previously noted, most obese individuals develop insulin resistance and subsequent hyperinsulinemia. Yet, they do not all develop T2DM or hypertension as defined by the most recent Joint National Committee (JNC 7) Report [16]. The reasons for this lack of consistency with disease development are likely due to varied genetic and environmental factors that will be discussed.

Genetics factors

Work by various investigators to isolate a "hypertensive gene" or group of genes has been ongoing for many years [17]. Many candidate genes for hypertension have been found, including genes for ion channels within the kidney that affect transporters (SLC12A3, SLC12A1, KCNJ1, SCNN1A, SCNN1B, SCNN1G, CLCNKB), ion channel regulation (WNK1, WNK4, SGK1, ADD1, ADD2, GRK4), aldosterone signaling (REN, AGT, ACE, AGTR1), catecholamine pathways (TH, COMT, DBH, DRD1, DRD2, ADRB1, ADRB2, ADRB3, ADRA1A), vasoconstriction (NOS3, EDN1, EDNRA, CYP2C8), and inflammation (TGF-beta) [18].

There are also studies investigating for genes that increase risk for development of both hypertension and diabetes. Kraja et al. evaluated the 22,161 participants in the seven studies of the STAMPEED consortium to determine if subjects with the metabolic syndrome phenotype had common genetic variants. Using genome-wide association analyses, they identified two single-nucleotide polymorphisms (SNPs) located between $LOC_{100128354}$ (similar to small nuclear ribonucleoprotein polypeptide G, 11q21) and MTNR1B (melatonin-receptor 1B) that were significantly associated with both elevated blood glucose and hypertension [19].

A study by Patel et al. investigated variations in the ACE2 (angiotensin-converting enzyme 2) gene in Caucasian men and women with T2DM. ACE2 is a homologue of ACE, and degrades angiotensin II to the vasodilator angiotensin I-7. The researchers found certain polymorphisms of ACE2 in men and women with T2DM that were associated with hypertension [20]. Bengtsson et al. investigated polymorphisms of the ACE gene and angiotensinogen (AGT) gene and their association with hypertension and T2DM. They found the D-allele of the ACE gene ID polymorphism increases susceptibility to hypertension, particularly when associated with T2DM [21]. A smaller study of 69 subjects with insulin-dependent diabetes found the CC-genotype of the A1166C gene polymorphism of the angiotensin type 1 receptor gene polymorphism is associated with hypertension [22].

A number of other factors have been associated with hypertension development in diabetes. Haptoglobin polymorphisms were examined in a 120-subject study, the results of which predicted the development of hypertension in patients with diabetes. The Hp1-2 genotype was the most common among those with refractory hypertension and T2DM [23]. Renalase is an important enzyme in catecholamine metabolism and is linked with changes associated with worsening of cardiac ischemia and kidney disease [24–26]. Buraczynska et al. found an association between the renalase gene polymorphism (C allele of rs2296545 SNP) with hypertension in 892 patients with T2DM [26]. Lastly, a recent study by Groop et al. investigated the association between polymorphism of the glycogen synthase gene and the associated risk of developing T2DM [27]. These investigators found two polymorphic alleles (A_1 & A_2) in this gene located on chromosome 19. Moreover, they documented a twofold greater prevalence of hypertension among subjects without diabetes who had the A_2 allele expressed. Unfortunately, no such distinction was noted in the group studied with diabetes. Note, however, that among the group with diabetes, both the A_1 & A_2 allelic groups had hyperinsulinemia and were hypertensive. Taken together, these studies provide evidence that supports the concept that a different "genetic load" is required for the development of either hypertension or diabetes. Specifically, each of these disorders appears to be inherited in a polygenic (i.e., to involve more than one gene) and heterogeneous (involving different constellations of disease genes in different persons) fashion. Since hypertension does not develop in all people with diabetes, presence of certain environmental factors, that is, diet, sedentary lifestyle, high salt intake, etc., are mostly required to express the concomitant generation of both diseases.

Ion transport homeostasis

Substantial evidence from animal models of hypertension as well as diabetic and nondiabetic hypertensive individuals supports an association between the presence of hypertension and changes in intracellular pH as well as electrolyte composition [17,28–36]. These observations have led to various hypotheses regarding the relative importance of one ion over another. This section reviews the studies for each ion implicated in causing hypertension as well as the effects of intracellular pH change.

Numerous investigators have documented increases in cytosolic free sodium concentrations from cells of hypertensive or diabetic patients when compared to age- and sex-matched nondiabetic controls [30,34,37,38]. These increases result from altered activity of the Na/H antiporter and the Na/Li countertransporter. The increases in intracellular sodium are highly correlated with the presence of an elevated diastolic blood pressure. Conversely, no relationship exists between increases in intracellular sodium concentration and the development of microalbuminuria [33].

The relationship between intracellular magnesium and blood pressure is less clearly defined. Hyperglycemia is known to reduce intracellular magnesium [36]. Moreover, data from experimental models of hypertension as well as from diabetic subjects with hypertension demonstrate an inverse relationship between intracellular magnesium concentration and blood pressure elevation [38]. The primary mechanism responsible for this relative reduction in intracellular magnesium relates to sodium-dependent magnesium efflux through the plasmalemmal membrane [38].

Studies in experimental models of diabetes consistently demonstrate abnormally elevated concentrations of intracellular calcium [28]. Moreover, increases in the intracellular calcium concentration are commonly seen in diabetic hypertensive subjects as well as in obese and essential hypertensive subjects [30]. Different combinations of circulating insulin and glucose levels in diabetes, obesity and essential hypertension may help explain observed differences in calcium regulation [30]. Hyperglycemia increases intracellular calcium concentration [36]. Since intracellular calcium has an optimal range for mediating insulin action, these changes result in an impaired cellular ability to generate acute calcium signals [36]. This consequently attenuates insulin action and thus, impairs glucose transport, decreases insulin-stimulated glucose uptake and ultimately contributes to the genesis of insulin resistance [39]. Lastly, there is evidence that the density of calcium channels is increased in peripheral skeletal muscle of diabetics, which may relate to these intracellular changes in calcium [28]. Moreover, there may be an interaction with regulation of calcium channels and the insulin receptor gene that remains to be elucidated. An in-depth analysis of studies relating to altered intracellular calcium homeostasis in diabetes is beyond the scope of this chapter. Taken together, these studies suggest that the concentration dependent influx of calcium into cells may be an initiating event that contributes to the pathophysiology of hypertension in diabetes. This is indirectly supported by early studies showing that moderate dose nifedipine failed to lower blood pressure in normotensive individuals but will lower pressure in hypertensive people [40,41].

The key cellular changes, therefore, in individuals with insulin resistance and hypertension may be summarized as an increase in the intracellular sodium and calcium and a decrease in magnesium composition [30,36,38,39,42–46]. Additionally, reductions in intracellular pH are also well documented from in situ studies of cells from both animal models of hypertension as well as hypertensive subjects [39,47,48]. The observed reductions in intracellular pH come from in situ studies and are contrary to other reports using tissue culture techniques. These latter studies report an increase in intracellular pH in subjects with diabetes [48]. This discrepancy may be due to the differences in pH measurement using a tissue culture technique versus in situ measurements. In situ studies, however, generally require minimal processing and hence are a better reflection of the disease state

in human beings. Interestingly, glucose ingestion increases pH in normotensive nondiabetic subjects [36,39].

The aforementioned changes in cellular milieu are linked to altered function of membrane ion transporters (Na/H antiporter, Na/K/ATPase, Mg/Na exchanger, Ca/H exchanger, Ca ATPase, and others). Both the sodium potassium ATPase and the Ca ATPase pumps are important in maintaining calcium homeostasis of the cell. Increased calcium ATPase activity has been reported in the renal cortex of non-insulin-dependent diabetic rats and in the platelets of non-insulin-dependent diabetic patients [49]. The converse is true, however, in insulin-dependent diabetic subjects [30]. These differences may relate to potentially different physiologic mechanisms that generate elevations in blood pressure.

Hormonal regulation of intracellular calcium may be abnormal in diabetes. Insulin and atrial natriuretic peptide lose their ability to stimulate the activity of calcium ATPase pumps in the renal cortex of non-insulin-dependent diabetic rats. Moreover, these hormones catalyze an exaggerated increase in platelet intracellular calcium in the presence of thrombin, adenosine diphosphate, and low-density lipoproteins in patients with both T1 and T2DM. Lastly, studies in hypertensive animal models as well as in patients who have hypertension and T2DM support the concept that these cellular changes are predominantly seen in salt-sensitive forms of hypertension [33,39,43,47,48].

It is difficult to assess whether alterations in these ion transporters antedates the development of hypertension or diabetes or whether they are a consequence of metabolic changes that subsequently generate a cellular milieu that leads to hypertension. One proposed hypothesis to explain these ion changes is that a primary (genetic) mutation is present on the gene locus that controls the Na/H antiporter and that this defect is expressed in the presence of persistent hyperglycemia [29,36,50]. This environmentally induced gene expression then alters cellular ion and pH homeostasis and directly contributes to the genesis of the insulin-resistant syndrome, T2DM, hypertension, and lipid abnormalities [29,50].

A number of recent studies support the hypothesis that cellular ion changes antedate the development of hypertension in diabetes [35,51,52]. However, only one of these studies provides direct evidence that hyperglycemia serves as the initiating event to alter Na/H antiporter activity [52]. Further support that Na/H antiporter activity is increased in diabetic hypertensive subjects comes from clinical studies that document increased activity of this pump in both nondiabetic and diabetic hypertensive subjects [28,31,53]. Genetic studies using linkage analysis, however, have failed to provide any evidence that mutations of the Na/H antiporter gene directly contribute to the pathogenesis of hypertension [54,55]. Similar disappointing results were noted for the Na/Li countertransporter [54]. Therefore, until evidence that is more conclusive is available the role of these ion transporters directly linking to the pathogenesis of

hypertension in diabetes is questionable. The development of hypertension in patients with T1DM is primarily related to the progression of nephropathy [56]. In contrast, the mechanism of hypertension in T2DM is primarily related to insulin resistance and central obesity [57].

Extracellular sodium homeostasis

Under normal conditions, various stimuli that raise blood pressure also increase sodium and water excretion through pressure natriuresis and diuresis. This natriuretic response continues until the reduction in venous return and cardiac output attenuate increases in blood pressure and fluid balance is restored. A number of hormonal and hemodynamic factors influence sodium excretion in people who have hyperinsulinemia, that is, obese or diabetic subjects. Hyperinsulinemic individuals are both salt sensitive and have an increase in total body sodium [58].

Numerous studies demonstrate a direct link between hyperinsulinemia and increased tubular sodium reabsorption. DeFronzo et al. were the first to report that at high physiologic insulin concentrations in the presence of euglycemia healthy humans reduced urinary sodium excretion by about 50% [29]. This observation is further corroborated by more recent studies with insulin concentrations of $<70\,\mu U\,mL^{-1}$ [59]. It is noteworthy that plasma insulin levels of $35\,\mu U\,mL^{-1}$ can elicit a mild antinatriuretic effect, a level noted in fasting insulin concentrations among obese individuals [60]. This antinatriuretic effect of insulin is related to an increased sodium reabsorption present primarily in the distal and to a less extent in the proximal tubule [61,62].

Chronic hyperinsulinemia serves as a better model to study the effects of insulin on sodium balance since it permits time for the kidney to "escape" the sodium-retaining effects of insulin. Other studies utilizing sodium loading of uncomplicated diabetic hypertensive subjects failed to demonstrate a difference in natriuretic response between diabetic and normal control subjects. Studies by Hall et al., following one month of chronic insulin infusion in dogs with reduced renal mass fed a high-salt diet failed to demonstrate a reduction in sodium excretion or an increase in blood pressure [60,63]. While hyperinsulinemic, these dogs were not hyperglycemic; however, insulin resistance is associated with higher levels of insulin which at the level of the proximal and distal tubule enhance sodium reabsorption, and hence it contributes to increases in blood pressure [64].

Chronic hyperglycemia is consistently associated with an increase in exchangeable body sodium [65]. Contrary, to hyperinsulinemic euglycemic models, hyperglycemic dogs in this study demonstrate a reduced sodium excretion in response to saline loading [65]. Taken together, it appears that hyperglycemia through effects on the sodium glucose exchanger in either the proximal tubule or other yet unknown mechanism increases total body sodium. Moreover, pressure natriuresis

effectively balances insulin-mediated sodium retention under conditions of chronic hyperinsulinemia. Thus, hyperinsulinemia alone is not expected to be invariably associated with an expansion of the body sodium pool but rather hyperglycemia mediates this effect and hence, hyperinsulinemia alone does not contribute to the genesis of hypertension in this way.

Multiple mechanisms are postulated to explain the antinatriuretic response of insulin. One such mechanism is the direct inhibitory effect of insulin on atrial natriuretic peptide (ANP). Numerous studies in both animal models of diabetes as well as in humans demonstrate an increased level of ANP as well as inhibition of its effect by insulin [66,67]. Chronic infusion of insulin results in a transient reduction in sodium excretion from which the kidney "escapes" [62]. The antinatriuretic response to insulin in normotensive subjects is secondary to increased distal tubular sodium reabsorption [62]. This response to insulin, however, is inhibited by ANP through its direct action on the inner medullary collecting duct; ANP does not inhibit this response in hypertensive subjects [68,69]. Thus, in hypertensive subjects the resistance to ANP appears to be localized in the inner medullary collecting duct.

Chronic hyperglycemia is consistently associated with an average 10% increase in body sodium [70]. Moreover, sodium excretion and response to saline loading or water emerging is blunted in such patients. This may relate to decreased effectiveness of natriuretic hormones such as ANP. However, in non-azotemic subjects with diabetes, given normal circulatory blood volumes, sodium concentrations are normal. This coupled with the hyperosmolarity-induced hyperglycemia and reduction in oncotic pressure suggests that chronic hyperglycemia is associated with an expanded extravascular fluid volume at the expense of intracellular and intravascular fluid volumes. Thus, under these circumstances, pressure natriuresis is no longer capable of balancing out the excess sodium retained by the kidneys. Thus, patients with diabetes have an expanded total body sodium pool, regardless of whether they are normotensive or hypertensive. Consequently, it does not appear to contribute directly to the mechanism of hypertension.

Sympathetic activity

Another system that contributes to the genesis of hypertension in individuals with diabetes is increased sympathetic nervous system activity. A direct correlation exists between increases in plasma insulin levels and sympathetic nervous system activity resulting from increased caloric intake [71]. Rowe and colleagues demonstrated insulin caused a dose-related increase in plasma norepinephrine levels whereas hyperglycemia had no such effects [72]. This increase in norepinephrine levels was closely related to an increase in pulse and blood pressure [72]. Thus, insulin may affect changes at the cellular receptor or synaptic level to mediate this increase in sympathetic activity. Consequently, hyperglycemia increases volume through sodium

retention and hyperinsulinemia increases sympathetic activity and together they generate sustained increases in blood pressure in people with poor glycemic control. Moreover, increases in sympathetic nervous system tone through drugs that result in vasoconstriction or sympathomimetics such as decongestants will worsen pre-existing insulin resistance or cause insulin resistance that is alleviated by renal denervation [73,74].

Vasoconstrictors such as norepinephrine, angiotensin II, vasopressin and many others are all growth factors whose action is modified by insulin [75]. The interaction of insulin with these various growth factors may relate to its vascular effects. Experimental studies have established that insulin can adrenergically mediate vascular smooth muscle contraction [76]. These effects of insulin are not related to its role in increasing glucose uptake because glucose removal from the incubation medium did not alter insulin's effect. Conversely, the attenuating effect on vascular smooth muscle contraction was not observed in the presence of calcium channel antagonists and ouabain [77]. This is consistent with the concept that insulin decreases signal transduction by attenuating calcium influx across cell membranes. Moreover, insulin has been shown to directly alter both the action and cellular production of the vasoactive peptide, endothelin [78]. Unfortunately, in two separate clinical studies plasma concentrations of endothelin did not correlate with the presence of hypertension [79,80]. These observations further support the concept of cellular changes induced by insulin with no peripheral marker to reflect this action.

Insulin is well documented to induce different systemic and renal hemodynamic effects in euglycemic versus hyperglycemic individuals. Baron et al., examined the relationship between insulin and norepinephrine on blood pressure and insulin sensitivity in a group of lean and obese men [81]. Both groups were normotensive; however, the obese group had higher basal blood pressure values. They noted augmented pressor sensitivity and a decreased metabolic clearance to norepinephrine in obese compared to lean subjects. These studies suggest that abnormalities in beta adrenoreceptor activity are responsible for differences in hemodynamic effects of insulin. Moreover, epinephrine may potentially create a vicious cycle by inhibiting the effects of insulin and thus potentiating insulin resistance. Lastly, insulin resistance has been shown to alter pressor sensitivity in diabetic and obese nondiabetic individuals. However, it is not a direct cause of hypertension unless other genetic factors are also present.

Obesity is generally thought to be associated with increased sympathetic activity; however, an analysis between lean and obese hypertensives could not predict a difference in sympathetic activity [81–83]. Thus, this enhanced sympathetic activity in obese individuals may be simply due to overweight itself. In people with diabetes who have hypertension sympathetic activity is quite elevated compared to normotensive people with diabetes or those without diabetes [82,84]. Moreover, the level of sympathetic activity is proportional to the duration of diabetes [84]. Recent pilot studies of renal sympathetic

nerve denervation demonstrated a clear improvement in blood pressure and glycemic control among patients with T2DM [85].

Therapeutic considerations

It is well established that in order to minimize cardio-renal risk of diabetes one has to maximally manage all known risk factors, that is, blood pressure, glucose, and lipids, Figure 74.1 [86].

Central to all CV risk factor modification are lifestyle changes, such as weight loss, exercise, reduction of alcohol, tobacco cessation, and a low-sodium diet below $2.4 \, g \, d^{-1}$ (Table 74.1). Very few studies investigate the effects of sustained weight loss on hypertension. The Swedish Obese Subjects study followed patients for 8 years after an average weight loss of 20 kg following bariatric surgery. They found no significant improvement in blood pressure [87]. After smoking cessation, perhaps the most important is reduction of sodium and increasing potassium in the diet. Data clearly indicate that failure to reduce sodium intake will result in failure in most people to achieve blood pressure goals in spite of multiple medications [88]. This is due to increased sodium intake blunting the activity of the RAS and increasing sympathetic activity. Additionally, failure to achieve a serum potassium level of at least $3.8 \, mEq \, L^{-1}$ will also blunt the antihypertensive activity of agents due to sustained vasoconstriction at low levels of potassium [89].

The goal blood pressure in patients with diabetes has recently come under scrutiny. For several years the American Diabetes Association and Joint National Committee (JNC VI and 7) have recommended a goal blood pressure of less than 130/80 mmHg in people with diabetes [90]. However, a review of all studies supporting this level of control reveals that all data come from retrospective analyses of trials and have a selection bias. Moreover, the only prospective outcome trials that randomized groups to different blood pressure levels were UKPDS and ACCORD but only the intensive treatment group in the ACCORD study attained a blood pressure of less than 130/80 mmHg.

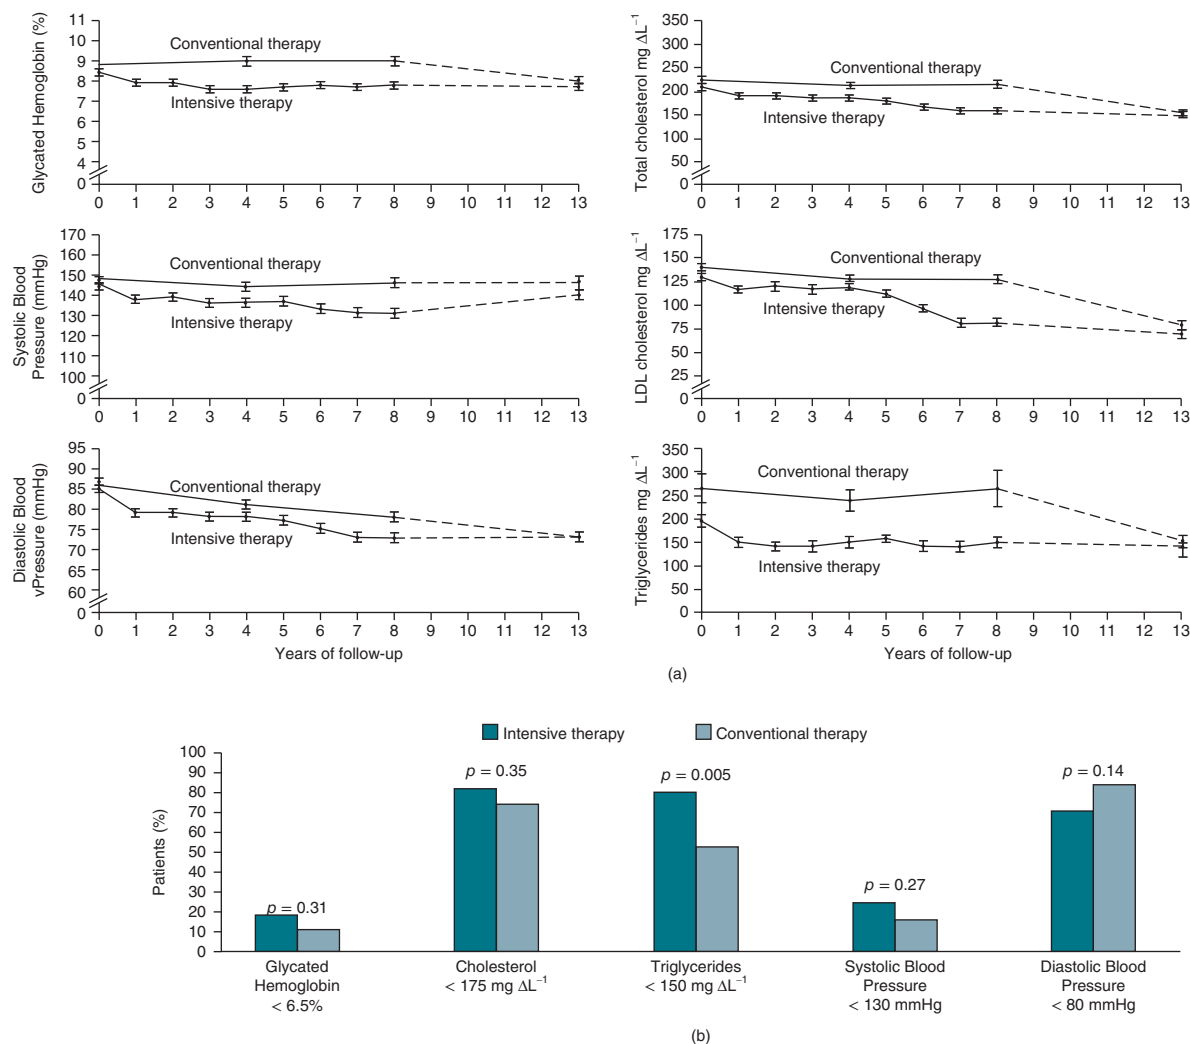
In ACCORD, there was no significant difference in the primary endpoint, a composite of cardiovascular events, between the standard and intensive blood pressure groups, Figure 74.2 [91]. Moreover, there was a significantly higher side-effect profile in the intensive treatment group. Additional findings from post hoc analyses of diabetes subgroups of trials such as the Ongoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) and the International Verapamil SR-Trandolapril Study (INVEST) corroborate the blood pressure finding of ACCORD. Taken together, these three studies demonstrate no additional benefit of blood pressure lowering below 130/80 mmHg on CV risk reduction compared to being between 130–139/80–85 mmHg level [92,93]. INVEST also demonstrated an increase in CV events at systolic blood pressures <115 mmHg, although 100% of these patients had coronary artery disease [92].


Figure 74.1 Results of 13-year follow-up of intensive versus conventional risk factor follow-up in patients with T2DM on CV and renal outcomes. Source: Adapted from Baron 1994 [81].

The exception, however, is stroke reduction, which in ACCORD demonstrated a linear benefit between level of blood pressure and risk reduction, this was not seen in the INVEST analysis. Given that more recent guidelines will all be evidence based it is a reality that the blood pressure goal for those with diabetes will probably be <140/90 mmHg.

There are a number of classes of antihypertensive agents, and studies have shown some classes should be preferentially used in patients with diabetes. Many post hoc analyses demonstrate that diuretics and β-blockers both worsen blood glucose control among those with diabetes and increase the development of new-onset diabetes in those with impaired fasting glucose [94–96]. Thiazide diuretics worsen glycemic status through hypokalemia and other mechanisms related to increased visceral adiposity [97]. Vasoconstricting β-blockers worsen insulin sensitivity [98]. However, the vasodilating β-blockers, such as carvedilol and nebivolol have neutral effects on glycemic control and increase insulin sensitivity [99–101].

Although diuretics are known to worsen glycemic control, post hoc analyses of two different cardiovascular outcome trials noted that cardiovascular event rates were not higher [102,103]. An analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) subgroup with diabetes failed to show a higher cardiovascular event rate in the diuretic group even though they had the greatest worsening of glycemic control [103]. In a more recent 12-year follow-up of the ALLHAT, participants on chlorthalidone with incident diabetes had consistently lower, nonsignificant risk for CVD mortality versus no diabetes or participants on amlodipine or lisinopril with incident diabetes. Moreover, participants with incident diabetes had elevated CHD risk compared with those with no diabetes, but those on chlorthalidone had significantly lower risk than those on lisinopril. Thus, thiazide-related incident diabetes has less adverse long-term CVD impact than incident diabetes that develops while on other antihypertensive medications [104].

Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m2).
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat.
Dietary sodium reduction	Reduce dietary sodium intake to no more than 100 mmol per day (2.4 g sodium or 6 g sodium chloride).
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most days of the week).
Moderate alcohol use	Limit consumption to no more than 2 drinks (e.g., 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey) per day in most men and to no more than 1 drink per day in women and lighter weight persons.

Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and calcium channel blockers (CCBs) have beneficial or neutral effects on insulin sensitivity and glycemic control [94,98,105]. However, renin-angiotensin system (RAS) blockers administered concomitantly with thiazide diuretics do not prevent worsening of glycemic control in obese persons with impaired fasting glucose [106].

The presence of microalbuminuria $(>30<300 \, \text{mg d}^{-1})$ is associated with higher rates of cardiovascular disease [107–109]. Moreover, presence of macroalbuminuria (greater than $300 \, \text{mg d}^{-1}$) in patients with diabetes is associated with

a very high cardiovascular mortality rate as well as high risk of CKD progression [110]. It should be noted, however, that albuminuria reduction in response to blood pressure lowering therapy is *not* a surrogate for improved renal outcomes as has been seen in many recent studies [111–114]. Thus, these individuals must achieve blood pressure goals in order to reduce CV risk. For this reason, all patients with diabetes should be evaluated annually for albuminuria and any change in albuminuria. RAS blockers alone and in combination with CCBs will reduce albuminuria but for maximal reduction in albuminuria, a nondihydropyridine CCB (diltiazem, verapamil) should be used in concert with a RAS blocker to achieve BP goal [2,115].

To further support the concept that albuminuria reduction may not correlate with better renal outcomes, the results of the VA NEPHRON-D are instructive [116]. The combination of ACEI and ARBs were evaluated on renal outcomes in patients with diabetic nephropathy in this trial. This study investigated the combination of losartan and lisinopril in patients with T2DM with a GFR of $30–89 \, \text{mL} \, \text{min}^{-1}$ per $1.73 \, \text{m}^2$ and a urinary albumin-to-creatinine ratio of at least $300 \, \text{mg g}^{-1}$ of Cr. The subjects treated with combination losartan and Lisinopril compared to losartan and placebo had higher rates of acute kidney injury and hyperkalemia. Also, the combination ARB/ACEI group did not result in a significant reduction in the primary endpoints of renal-disease progression or death [116].

Recent evidence from the international kidney guidelines (KDIGO) indicates that the strongest level of evidence supporting RAS blocker associated slowing of CKD progression in diabetic nephropathy is restricted to those with stage 3 or higher CKD who have albuminuria $>300 \, \text{mg day}^{-1}$ [117]. There is no evidence supporting their use in people with early

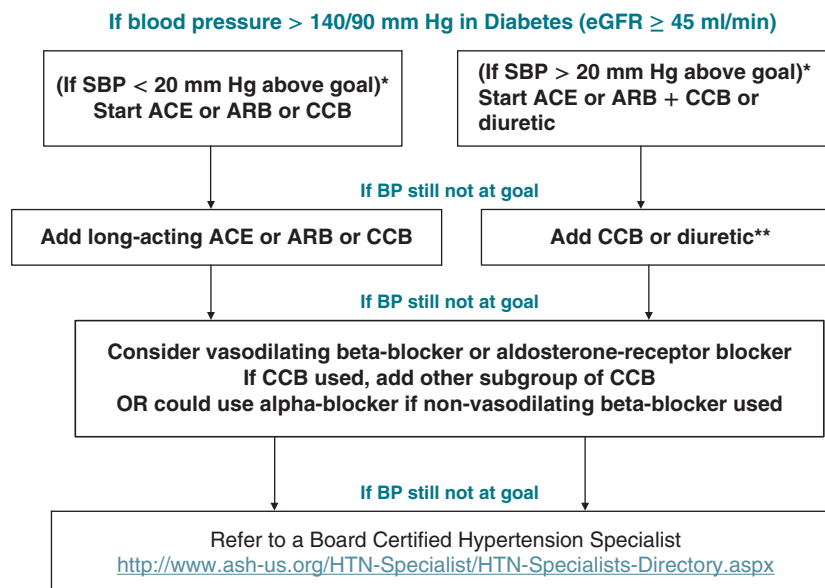
If blood pressure > 140/90 mm Hg in Diabetes (eGFR ≥ 45 ml/min)


Figure 74.2 A suggested approach to achieve BP goal in patients with diabetes with Stages 1–3a chronic kidney disease. Source: Bakris 2010 [128]. Reproduced with permission of Elsevier.

nephropathy or those with microalbuminuria with or without hypertension [118]. Thus, the true evidence for blockers of the RAS is limited in people with diabetes. This is further supported by a meta-analysis indicating that BP lowering and not the class of antihypertensive agent used to reduce BP is responsible for a reduction in cardiovascular events [119]. Therefore, one should focus on lowering blood pressure using antihypertensive agents that do not worsen preexisting metabolic conditions and are shown to protect against kidney disease progression, that is, albuminuric kidney disease.

Combination therapy is commonplace in people with diabetes with or without kidney disease. An analysis of the diabetes subgroups of many cardiovascular outcome trials indicates an average of 2.9 medications are needed to achieve blood pressure goals. In subjects with stage 3 or greater kidney disease, this number rose to 3.3 medications [120]. Based on the American Society of Hypertension consensus report on the use of combination antihypertensive medications, a suggested approach to blood pressure control in patients with diabetes is detailed in Figure 74.2 [121]. This algorithm serves as a guide and does not substitute good clinical judgment for each unique patient.

Use of single pill combinations (SPC) also improves patient adherence and minimizes the number of BP pills ingested daily [122,123]. Fundamentally, two types of SPCs have good evidence for outcomes with one showing superior CV outcomes in diabetes, that is, RAS blockers with CCBs and RAS blockers with thiazide diuretics [121]. Between these two combinations RAS blockers with ACE inhibitors have level 2A [124]. Based on these data use of SPC should be strongly considered especially in people who are 20/10 mmHg above their BP goal [125]. Note that use of an ACE inhibitor/ARB combination is not supported for BP or CV risk reduction and is contraindicated in people with advanced diabetic nephropathy due to high rates of hyperkalemia [121].

Conclusion

It appears that development of hypertension in subjects with diabetes is due to both genetic and environmental modifiers of these genetic factors. The presence of insulin resistance should be considered a modifiable risk factor for, rather than the mechanism for development of hypertension in such patients. Insulin resistance can be markedly improved by weight reduction and exercise. Moreover, it is clear that an as yet undefined genotype needs to be present for the development of hypertension independent of that for diabetes. Thus, while obesity is clearly associated with insulin resistance and elevations in blood pressure, frank hypertension may not develop unless a certain "genetic load" is present. Major factors, but not the only contributors to hypertension development in this setting, include hyperglycemia-associated sodium retention/volume expansion and hyperinsulinemia-associated increases in sympathetic tone.

The ionic transporters primarily implicated in the genesis of hypertension involve calcium homeostasis. These transporters are affected by hyperglycemia as well as hyperinsulinemia. Cellular changes in these transporters ultimately affect sodium homeostasis. However, sodium retention, per se, is not a prominent factor that contributes to the genesis of hypertension in diabetes but increased salt sensitivity due to a reduction in nitric oxide is a factor. Thus, altered vascular responsiveness to sodium loads in such patients plays an important role in its genesis. Lastly, the vascular reactivity effects of sodium coupled with the enhanced pressor dose–response seen in subjects with diabetes combine to raise blood pressure in such individuals. These blood pressure effects early in the course of diabetes are largely vascular in nature with evidence of abnormal sodium handling by the kidney as noted earlier in this chapter. As eGFR falls below 60 mL min^{-1} however, the kidney itself is further contributing to increasing blood pressure due to enhanced effects associated with increased sympathetic tone and sodium reabsorption [83,126,127].

The high cardiovascular risk in these patients requires an integrated therapeutic intervention that includes both lifestyle changes, appropriate medications for BP lowering, along with glucose and lipid control. The medications used to lower blood pressure should address albuminuria reduction, if present, and avoid worsening of glycemic control if possible. The most important aspect of blood pressure control in people with diabetes is actually lowering the blood pressure to goal, for example <140/90 mmHg while minimizing side effects.

Peripheral vascular and cerebrovascular disease in diabetes mellitus

Debabrata Mukherjee
Texas Tech University, El Paso, TX, USA

Key points

- Diabetes is frequently associated with atherosclerotic vascular disease including coronary, peripheral, and cerebrovascular disease.

- Early diagnosis of PAD in diabetic patients is critically important for the prevention of progression of disease as well as for prediction and subsequent reduction of overall cardiovascular risk.

- The American Diabetes Association (ADA) consensus statement recommends that a screening ABI be performed in all diabetic individuals >50 years of age.

- Current evidence highlights the importance of adopting a multifactorial approach for the prevention of vascular complications in patients with type 2 diabetes. Lowering of blood pressure with regimens based on a variety of antihypertensive drugs, including ACE inhibitors, ARBs, β-blockers, diuretics, and calcium channel blockers, has been shown to be effective in reducing cardiovascular events in diabetics.

- Cardiovascular physicians should be aware of the strong association between diabetes and atherosclerosis and use appropriate medical and interventional treatments to reduce disability and death in these patients.

Introduction

Diabetes mellitus is an established risk factor for atherosclerosis, and the risk of atherosclerotic vascular disease and its major clinical consequences, which include coronary artery disease (CAD), peripheral arterial disease (PAD), and cerebrovascular disease, is markedly increased among individuals with diabetes. The increased risk appears to be independent of, and additive to, other cardiovascular risk factors [1]. Epidemiologic studies suggest that atherosclerosis causes most of the morbidity and mortality in patients with diabetes, particularly in the burgeoning type 2 diabetic patient population [2]. The Verona Diabetes Study demonstrated that cardiovascular disease is responsible for 44% of all-cause mortality in the diabetic patient population [3]. The duration of diabetes increases the risk of death from cardiovascular disease, independent of coexisting risk factors. Insulin resistance and its attendant metabolic abnormalities appear to play a pivotal role in the pathophysiology of the increased cardiovascular risk of diabetes [4].

Diabetes and risk of vascular disease

A meta-analysis of individual records of diabetes, fasting blood glucose concentration, and other risk factors in people without initial vascular disease attempted to quantify the magnitude of associations of diabetes mellitus and fasting glucose concentration with risk of coronary heart disease and major stroke subtypes [5]. Analyses included data for 698,782 people (52,765 nonfatal or fatal vascular outcomes; 8.49 million person-years at risk) from 102 prospective studies. Adjusted HRs with diabetes were: 2.00 (95% CI 1.83–2.19) for coronary heart disease; 2.27 (1.95–2.65) for ischemic stroke; 1.56 (1.19–2.05) for hemorrhagic stroke; 1.84 (1.59–2.13) for unclassified stroke; and 1.73 (1.51–1.98) for the aggregate of other vascular deaths. Overall, it appears that diabetes confers about a twofold excess risk for a wide range of vascular diseases, independent from other conventional risk factors [5]. In T2DM, both angiogenesis and microangiopathy are increased and may contribute to accelerated atherosclerosis and the development of vulnerable plaque [5]. Hyperglycemia is a driving force in both large- and small-vessel disease [6].

Diabetes and peripheral arterial disease

Peripheral arterial disease (PAD) affects approximately 12 million people in the US and approximately 20–30% of these

patients have diabetes [1]. In studies using the ankle–brachial index (ABI), the prevalence of PAD (defined as an ABI <0.90) in diabetic individuals ranges from 20% to 30% [7]. Overall, diabetes is associated with a two- to fourfold increase in the incidence of PAD and an abnormal ABI is present in ~15% of diabetes patients [2,8]. Both intermittent claudication and critical limb ischemia are increased in diabetes. The prevalence of PAD increases with advancing age, duration of diabetes, and other risk factors such as smoking, dyslipidemia, and hypertension. The degree of diabetic control is also an independent risk factor for PAD; with every 1% increase in glycosylated hemoglobin, the risk of PAD has been shown to increase by 28% [9]. Early diagnosis of PAD in diabetic patients is critically important for the prevention of progression of disease as well as for prediction and subsequent reduction of overall cardiovascular risk. The distribution of atherosclerosis differs in diabetics and nondiabetics with stenotic lesions in patients with diabetes often located more distally than in nondiabetic subjects. Thus, the typical diabetic PAD lesions are located in the popliteal artery or in the runoff vessels below the knee, that is, the anterior tibial, posterial tibial, and the peroneal arteries [10,11]. The involvement of the distal limb vessels, such as the tibial and peroneal arteries, limits the potential for collateral vessel development and reduces options for revascularization [10]. Another hallmark of diabetic PAD is the calcification of the media layer of the arterial wall which may confound some diagnostic tests, a highly characteristic feature of T2DM [12,13].

A patient with critical limb ischemia is defined as a patient with chronic ischemic rest pain, ulcers, and gangrene due to arterial disease. It is important to consider that ulcers may often exist in the diabetic foot despite a normal macrocirculation. These ulcers may be due to disease in the microcirculation or related to neuropathy or sometimes multifactorial due to combination of impaired circulation, neuropathy, and infection.

Diagnosis

A thorough medical history and physical examination is indicated in evaluating a diabetic individual for the presence of PAD. Information about the onset and duration of symptoms, pain characteristics, and any alleviating factors is helpful. Symptoms of leg ischemia in diabetic patients with peripheral neuropathy may be atypical and may delay diagnosis. Rather than experiencing cramping pain in legs or typical claudication, the patient may suffer from leg fatigue or inability to walk at their normal speed. If the patient has typical claudication, the claudication distance should be recorded at each visit and a shortening claudication distance signals progression of disease. The clinical stage of symptomatic PAD can be classified using the Fontaine staging system (Table 75.1). Fontaine stage I represents asymptomatic PAD; stages IIa and IIb include patients with mild and moderate-to-severe intermittent claudication, respectively; those with ischemic rest pain are classified as Fontaine stage III; and patients with tissue breakdown in the form of distal ulceration and gangrene represent Fontaine

Table 75.1 Fontaine classification of peripheral arterial disease

Stage I	Asymptomatic
Stage IIa	Mild claudication (>200 M)
Stage IIb	Moderate to severe claudication (≤200 M)
Stage III	Ischemic rest pain
Stage IV	Tissue loss or ulceration

stage IV. A typical history of claudication has a low sensitivity, but a high specificity for PAD in diabetic individuals [14].

A complete physical examination is very important for the diagnosis of PAD in these individuals. Palpation of pulses in the leg and visual inspection of the feet are essential. Dependent rubor, pallor when the foot is elevated, absence of hair growth, and dystrophic toenails are signs of peripheral ischemia. In addition to measurement of ABI, physical examination should include blood pressure measurement, palpation of peripheral pulses, and auscultation of pulses and bruits. Palpation of peripheral pulses should include an assessment of the femoral, popliteal, and pedal vessels and pulses graded as absent, diminished, or normal. Dorsalis pedis pulse abnormalities are less sensitive for PAD, since up to 30% of these abnormalities may be due to a congenital absence of the dorsalis pedis artery. The absence of both the dorsalis pedis pulse and the posterior tibial pulse strongly suggests the presence of PAD. Figure 75.1 shows a typical protocol for the diagnosis of PAD in patients with diabetes.

An objective measure of peripheral vascular disease is the ABI, defined as the ratio between the arterial pressure at the ankle level (dorsalis pedis or posterior tibial) and in the left or right brachial artery with the highest pressure. The ABI should normally be above 0.9. This measurement is valuable for early detection of PAD and also for a better stratification of the overall cardiovascular risk. An ABI below 0.5 is indicative of severely impaired circulation of the foot. An ABI >1.4 is also abnormal and indicates poorly compressible vessels as a result of stiff arterial walls, which usually in diabetic patients are due to atherosclerosis in the media layer of the arterial wall. In situations where an elevated ABI is recorded or a pseudonormal value is suspected, the blood pressure should also be measured at the level of the toe by a minicuff and a technique suitable for blood flow detection in the toe. This is called the toe–brachial index (TBI).

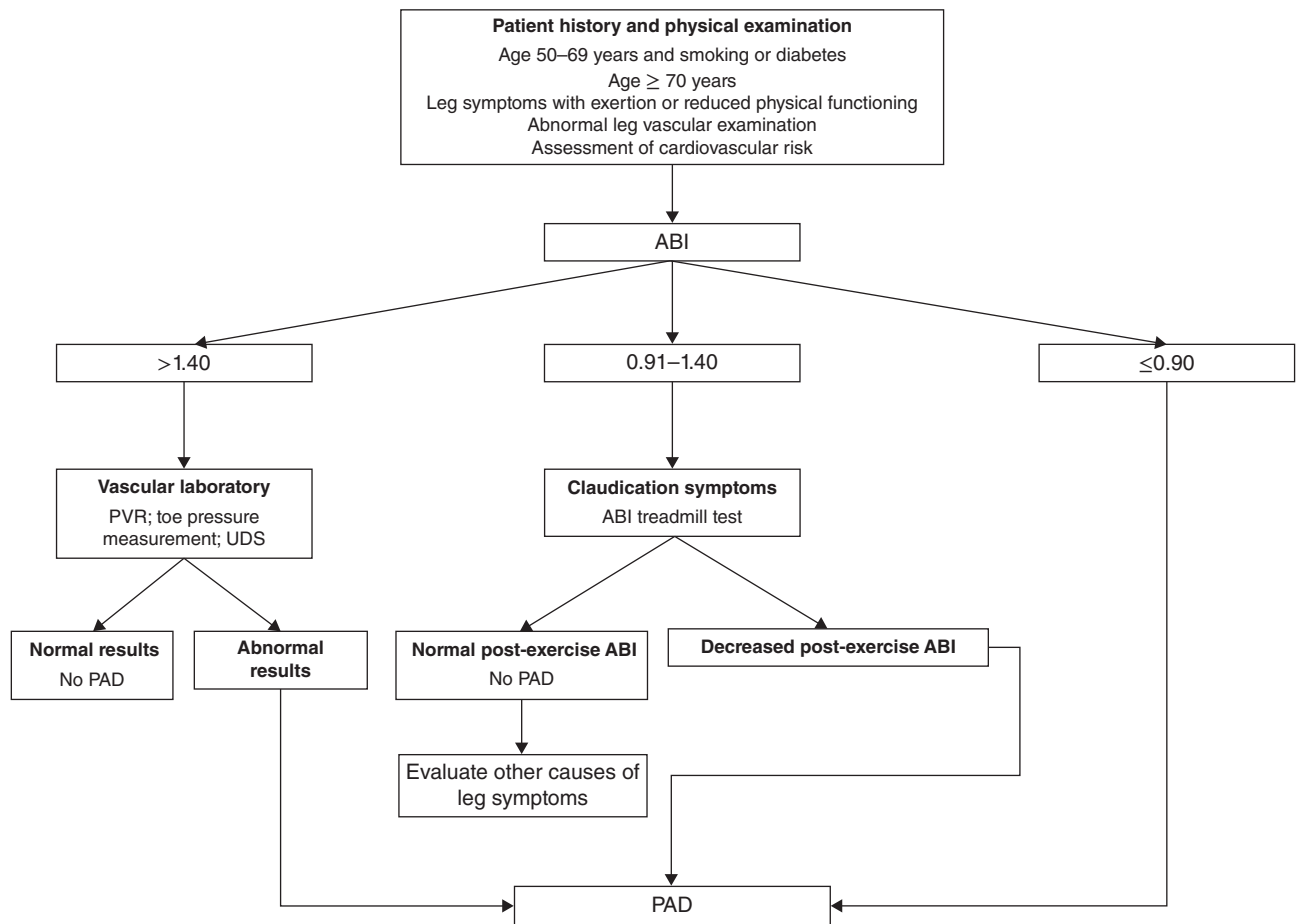
The American Diabetes Association (ADA) consensus statement recommends that a screening ABI be performed in all diabetic individuals >50 years of age [1]. If normal (0.91–1.40), the test should be repeated every 5 years. An ABI should also be performed in any patient with symptoms suggestive of PAD. It should be recognized that ABI determinations may be of limited value in some patients with diabetes, because calcification of the tibial arteries may render them noncompressible, resulting in unusually high ABI values (>1.40). Under these conditions, the ABI cannot distinguish patients who have arterial occlusion from those who do not, making the ABI unhelpful. As a result,


Figure 75.1 Typical protocol for the diagnosis of peripheral arterial disease in patients with diabetes. Source: Hiatt 2001 [14]. Reproduced with permission of Massachusetts Medical Society.

measurement of great toe artery pressure for calculation of TBI is commonly advocated in diabetic patients. Studies have suggested that assessment of TBI is the method of choice in the presence of overt calcification as defined by an ABI of >1.4 [15,16]. However, an elevated ABI is still predictive of an increased risk of cardiovascular events, and other noninvasive vascular tests should be considered to make the diagnosis of PAD. Transcutaneous oxygen ($TcPO_2$) measurement is another useful noninvasive modality that can prospectively determine severity of foot ischemia, and aid in selecting appropriate treatment for patients with diabetes and foot salvage problems [17].

In the patient with PAD in whom further investigation is required, for example in planning a revascularization procedure, the next step would be evaluation for segmental pressure and pulse volume recordings. Both tests aid in the localization of arterial occlusive lesions. Other noninvasive imaging techniques, such as ultrasonic duplex scanning or magnetic resonance angiography (MRA), can be used when more precise measurements of the morphological features of occlusions are required for planning revascularization options.

Ultrasound duplex scanning can directly visualize vessels, providing information on artery wall thickness, degree of flow turbulence, and changes in blood flow velocity which can be used to define severity of arterial stenosis [18]. Comprehensive imaging of the peripheral vasculature has traditionally been performed with invasive digital subtraction angiography. However, with the introduction of MRA and computed tomographic angiography (CTA), noninvasive imaging is now becoming a reality. Contrast-enhanced MRA produces images that are fairly comparable with conventional angiography. Recently, the resolution of CTA has dramatically improved image quality and expanded the applications for noninvasive angiography. At this point, CTA is replacing conventional angiography in some centers. Table 75.2 depicts the different methods for evaluating the peripheral circulation.

Treatment

One aim of medical management of PAD among diabetics is to aggressively modify cardiovascular risk factors to reduce the risk of future cardiovascular events (Table 75.3). It is also important

Table 75.2 Investigations of the peripheral circulation in diabetic patients

At the physician's office in every patient
- Inspection
  - Dependent rubor
  - Pallor with elevation
  - Absence of hair growth
  - Dystrophic toenails
    - Ulcers or gangrenes
- Palpation
  - Pulses (radial, brachial, femoral, popliteal, dorsalis pedis, posterior tibial)
  - Dry and cool skin
  - Sensibility
- Pressure measurement
  - Ankle and arm blood pressure

At the vascular laboratory (when appropriate)
- Distal and/or segmental pressure measurements
- Oscillography
- Treadmill testing (with or without distal pressure after exercise)
- Duplex sonography
- For evaluation of the microcirculation
  - Transcutaneous oxygen pressure
  - Vital capillaroscopy

At the radiology department
- Magnetic resonance imaging
- Angiography

to relieve the symptoms of intermittent claudication in order to improve functional status and quality of life. Smoking cessation, normalization of lipid abnormalities, and optimization of glycemic control are the most important steps that contribute to the prevention of primary or secondary cardiovascular disease in these patients. Table 75.3 describes general recommendations for treatment of diabetic patients with PAD.

PAD patients with diabetes tend to have more severe symptoms and a worse prognosis than nondiabetic patients [10], and the ACC/AHA guidelines concur with the American Diabetes Association (ADA) recommendations and note that aggressive management of diabetes has been shown to reduce the risk of

nephropathy, retinopathy, and other microvascular events [19]. Intensive glycemic control may also reduce the risk of cardiovascular events in patients with PAD and diabetes, although there is a lack of clinical data specific to this population [19].

The Steno-2 study showed that the risk of both cardiovascular and microvascular complications was significantly reduced by about 50% in type 2 diabetic patients who received targeted, intensified, multifactorial management of glycemia, dyslipidemia, hypertension and microalbuminuria via lifestyle modification, pharmacologic therapy and secondary prevention with antiplatelet therapy, compared with patients conventionally managed according to national guideline recommendations [20]. Analysis of the Diabetes Control and Complications Trial, in which 1441 patients with T1DM were randomized to intensive or conventional treatment, showed that the risk of major peripheral vascular events in the group receiving intensive therapy was 22% lower than that in the conventional therapy group (0.43 vs. 0.55 events per 100 patient-years). This difference, however, was not statistically significant [21].

Glycemia

The UKPDS 33 study of 3867 newly diagnosed patients with T2DM showed that intensive antidiabetic treatment reduced the risk of complications by 12% (95% CI 1–21; $p = 0.029$) compared with conventional therapy [22]. Although this was primarily due to a reduction in microvascular complications, there was also a 16% reduction in MI ($p = 0.052$) with intensive treatment. The UKPDS long-term trials indicate that in patients with T2DM, intensive glucose control may have a legacy effect, whereas the same benefit may not apply to tight blood pressure control [23]. The studies highlight the importance of adopting a multifactorial approach for the prevention of vascular complications in patients with T2DM and reinforce the importance of maintaining good glycemic control, not only for the prevention of the renal and metabolic complications of diabetes but also for protection against the development of major cardiovascular disease in the long term [23]. A recent study, the Veterans Affairs Diabetes Trial (VADT) suggested that intensive glucose control in patients with poorly controlled T2DM had no significant effect on the rates of major cardiovascular events, death, or microvascular complications, with the exception of progression of albuminuria [24]. The study randomly assigned 1791 military veterans (mean age, 60.4 years) who had a suboptimal response to therapy for T2DM to receive either intensive or standard glucose control. The median follow-up was 5.6 years. Median glycated hemoglobin levels were 8.4% in the standard-therapy group and 6.9% in the intensive-therapy group. The primary outcome occurred in 264 patients in the standard-therapy group and 235 patients in the intensive-therapy group (hazard ratio (HR) in the intensive-therapy group, 0.88; 95% CI 0.74–1.05; $p = 0.14$). There was no significant difference between the two groups in any component of the primary outcome or in the rate of death from any cause (HR 1.07; 95% CI 0.81–1.42; $p = 0.62$) [24]. The Action to Control Cardiovascular Risk in

Diabetes (ACCORD) trial, which involved 10,251 patients with T2DM, attempted to determine whether intensive insulin therapy was associated with a lower incidence of cardiovascular events than standard therapy [25]. The study was specifically designed to address whether an HbA1c goal of <6%, to be attained by intensive therapy, would reduce cardiovascular events in patients with established cardiovascular disease or cardiovascular risk factors, as compared to a standard strategy using an HbA1c target of 7.0–7.9%. At a mean treatment duration of 3.5 years, the study was stopped prematurely on the recommendation of the Data and Safety Monitoring Board, owing to an increase in all-cause mortality in the intensive-therapy group compared with the standard-therapy group (5% vs. 4%; HR 1.22; 95% CI 1.01–1.46). The rate of death from cardiovascular causes was similarly increased in the intensive-therapy group (2.6% vs. 1.8%; HR 1.35; 95% CI 1.04–1.76). The primary outcome of nonfatal myocardial infarction, nonfatal stroke or death from cardiovascular cause was not significantly different in the group assigned to intensive glycemic control (6.9% vs. 7.2%; HR 0.90; 95% CI 0.78–1.04) [25]. The Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial enrolled 11,140 patients with T2DM and pre-existing cardiovascular disease or at least one additional cardiovascular risk factor [26]. In contrast to the ACCORD trial, the primary outcome in the ADVANCE trial was a composite of microvascular events (nephropathy and retinopathy) and macrovascular disease defined by major adverse cardiovascular events (myocardial infarction, stroke, and cardiovascular death). Intensive therapy was associated with a decrease in the incidence of the primary endpoint (a combination of microvascular and macrovascular events, as outlined earlier; 18.1% vs. 20.0%; HR 0.90; 95% CI 0.82–0.98) and of major microvascular events (9.4% vs. 10.9%; HR 0.86; 95% CI 0.77–0.97), compared with standard therapy. This benefit was primarily the result of a reduction in the incidence of nephropathy (4.1% vs. 5.2%; HR 0.79; 95% CI 0.66–0.93), as intensive therapy had no statistically significant effect on the incidence of retinopathy or macrovascular events [26].

Despite the need for further study on the association of glycemic control and cardiovascular risk in patients with PAD and diabetes, both the ACC/AHA and the ADA recommend the reduction of HbA1c to <7.0% for this population [19,27,28]. The results from ACCORD, ADVANCE, and VADT should not be interpreted to abandon the general goal of <7% and diminish the importance of glycemic control. The lower-than-anticipated event rates observed in both intensive and standard treatment groups in these studies rather support the premise that a multifactorial approach should be used to address the major cardiovascular risk factors including regular physical activity, lipid lowering, blood pressure control, and so on.

Antiplatelet therapy

The use of antiplatelet agents is known to reduce future secondary cardiovascular events in patients with both diabetes mellitus and cardiovascular disease [29]. One study examined whether aspirin and antioxidant therapy, combined or alone, are more effective than placebo in reducing the development of cardiovascular events in patients with diabetes mellitus and asymptomatic PAD. A total of 1276 adults aged 40 or more with T1 or T2DM and an ankle–brachial pressure index of 0.99 or less but no symptomatic cardiovascular disease were enrolled [30]. Daily, 100 mg aspirin tablet plus antioxidant capsule ($n = 320$), aspirin tablet plus placebo capsule ($n = 318$), placebo tablet plus antioxidant capsule ($n = 320$), or placebo tablet plus placebo capsule ($n = 318$). Overall, 116 of 638 primary events occurred in the aspirin groups compared with 117 of 638 in the no aspirin groups (18.2% vs. 18.3%) (HR 0.98; 95% CI 0.76–1.26) [30]. This trial did not provide evidence to support the use of aspirin in primary prevention of cardiovascular events and mortality in the population with diabetes. Based on this and other available evidence, the American Diabetes Association suggests that low-dose (75–162 mg d^{-1}) aspirin use for prevention is reasonable for adults with diabetes and no previous history of vascular disease who are at increased risk for cardiovascular disease (10-year risk of CVD events >10%) and states that aspirin should not be recommended for CVD prevention for adults with diabetes at low CVD risk (men under age 50 years and women under 60 years with no major additional CVD risk factors [31]. The Antithrombotic Trialists' (ATT) Collaboration performed a meta-analysis and suggested that in primary prevention without previous disease, aspirin is of uncertain net value as the reduction in occlusive events needs to be weighed against any increase in major bleeds [32].

Lipids

The Cholesterol Treatment Trialists' (CTT) Collaborators analyzed data from 18,686 individuals with diabetes (1466 with type 1 and 17,220 with type 2) in the context of a further 71,370 without diabetes in 14 randomized trials of statin therapy [33]. During a mean follow-up of 4.3 years, there were 3247 major vascular events in people with diabetes. There was a 9% proportional reduction in all-cause mortality per mmol L^{-1} reduction in LDL-cholesterol in participants with diabetes (rate ratio (RR) 0.91; 95% CI 0.82–1.01; $p = 0.02$), which was similar to the 13% reduction in those without diabetes (RR 0.87; 0.82–0.92; $p < 0.0001$). This finding reflected a significant reduction in vascular mortality (RR 0.87; 0.76–1.00; $p = 0.008$) and no effect on nonvascular mortality (RR 0.97; 0.82–1.16; $p = 0.7$) in participants with diabetes. There was a significant 21% proportional reduction in major vascular events per mmol L^{-1} reduction in LDL-cholesterol in people with diabetes (RR 0.79; 0.72–0.86; $p < 0.0001$), which was similar to the effect observed in those without diabetes (RR 0.79; 0.76–0.82; $p < 0.0001$). In diabetic participants there were reductions in myocardial infarction or coronary death (RR 0.78; 0.69–0.87; $p < 0.0001$), coronary revascularization (RR 0.75; 0.64–0.88; $p < 0.0001$), and stroke (RR 0.79; 0.67–0.93; $p = 0.0002$). These findings would suggest that statin therapy be considered for all

diabetic individuals who are at sufficiently high risk of vascular events [33]. However, it should be noted that while statins are effective for cardiovascular disease prevention, they have recently been associated with an increased risk of new-onset diabetes mellitus [34,35]. Based on new data, the FDA changed statin labeling, incorporating the fact that there are studies showing that patients being treated with statins may have a small increased risk of increased blood sugar levels and of being diagnosed with T2DM. Based on totality of data, for the vast majority of patients who are on statins, the benefits are expected to outweigh the risks since statins are very effective at lowering risk for vascular disease and stroke. The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial investigated whether treatment with rosuvastatin, 20 mg daily, as compared with placebo, would decrease the rate of first major cardiovascular events in apparently healthy men and women with LDL-cholesterol levels of less than $130 \, \text{mg dL}^{-1}$ $(3.4 \, \text{mmol L}^{-1})$ and high-sensitivity C-reactive protein levels of $2.0 \, \text{mg L}^{-1}$ or higher [36]. The study reported that rosuvastatin significantly reduced the incidence of major cardiovascular events [36]. The concern about new-onset diabetes should lead to open discussion between physician and patient and the risk–benefit assessed for each individual patient. It should also lead to increased vigilance about testing for diabetes in patients who are on statins.

Fibrates, introduced more than 35 years ago, based on favorable changes in the lipid profile, continue to generate controversy regarding their clinical efficacy. Two randomized, placebo-controlled trials of gemfibrozil had demonstrated improvements in cardiovascular outcomes but subsequent trials of bezafibrate and fenofibrate showed no significant overall cardiovascular benefit over placebo [37]. Based on contemporary evidence, it would appear that the benefit of adding a fibrate to statin therapy in reducing the risk of cardiovascular events in patients with T2DM is unproven. At this time, clinicians who choose to prescribe combination therapy should selectively target high-risk patients only after optimal control of LDL-cholesterol has been achieved with statin therapy [37].

Blood pressure

Hypertension is a common comorbidity of diabetes, affecting a significant proportion of patients, with prevalence depending on type of diabetes, age, obesity, and ethnicity. In T1DM, hypertension is often the result of underlying nephropathy, while in T2DM it usually coexists with other cardiometabolic risk factors. Epidemiologic analyses show that high blood pressure is associated with increased cardiovascular event rates and mortality in individuals with diabetes. Randomized clinical trials have demonstrated the benefit (reduction of CHD events, stroke, and nephropathy) of lowering blood pressure to <140 mmHg systolic and <80 mmHg diastolic in individuals with diabetes but the evidence for benefits from lower systolic blood pressure targets is limited [38]. The current guidelines recommend that people with diabetes and hypertension should be treated to a systolic blood pressure goal of <140 mmHg and diastolic blood pressure <80 mmHg [38]. Lowering of blood pressure with regimens based on a variety of antihypertensive drugs, including ACE inhibitors, ARBs, β-blockers, diuretics, and calcium channel blockers, has been shown to be effective in reducing cardiovascular events in diabetics. Although evidence for distinct advantages of RAS inhibitors on cardiovascular disease outcomes in diabetes remains conflicting, the high CVD risks associated with diabetes, and the high prevalence of undiagnosed CVD, may favor using them as first-line hypertension therapy in people with diabetes [38].

Lifestyle

To relieve the symptoms of intermittent claudication, patients should exercise regularly. A regular walking regimen is extremely helpful. The best program is a stop-start walking regimen and includes regular daily walks, $30–45 \, \text{min d}^{-1}$, at least three times per week, for at least 6 months. Individuals should walk as far as possible using near maximal pain as a signal to stop and resume walking when pain goes away. A typical supervised exercise program is 60 min in duration and is monitored by a skilled nurse or technician. Patients may be encouraged to walk primarily on a treadmill since this most closely reproduces walking in the community setting. The initial workload of the treadmill is set to a speed and grade that bring on claudication pain within 3–5 min. Patients walk at this work rate until they achieve claudication of moderate severity. They then rest until the claudication abates, and then resume exercise. This repeated on-and-off form of exercise is continued throughout the supervised rehabilitation setting. On a weekly basis, patients should be reassessed clinically as they are able to walk further and further at their chosen workload. This then will necessitate an increase in speed or grade or both to allow patients to successfully work at harder and harder workloads [39–41]. Currently, two pharmacologic agents are approved for the symptomatic treatment of intermittent claudication: namely pentoxifylline and cilostazol. Pentoxifylline, a hemorheologic agent, decreases blood viscosity and improves erythrocyte flexibility [42]. The results of clinical trials demonstrating the efficacy of pentoxifylline in improving treadmill-walking distance have been equivocal, and there are insufficient data to justify generalized use in PAD [43]. Cilostazol, a phosphodiesterase inhibitor, is the most effective agent available in the US. Cilostazol (100 mg twice daily) has been shown to improve maximal walking distance by 40–50% compared with placebo [44,45]. In a direct comparison, the mean maximal walking distance in PAD patients treated with cilostazol for 24 weeks was significantly greater compared with that of patients who received pentoxifylline or placebo [46]. Because of concerns about the potential risk of mortality, cilostazol is contraindicated if any degree of systolic or diastolic heart failure is present or in patients with left ventricular systolic dysfunction [40].

Revascularization

Diabetic patients with progressively disabling claudication and those with critical limb ischemia should be considered for revascularization. Decisions about endovascular or open surgical procedures depend in large part on the severity and distribution of the arterial lesions [47]. Outcomes of iliac artery percutaneous transluminal angioplasty (PTA) and stenting in patients with diabetes have been reported as similar to or worse than those in nondiabetic patients [48,49]. With respect to surgery, the long-term patency rates after femoral-popliteal PTA are also lower in diabetic than in nondiabetic patients [50]. The modality of revascularization among diabetic patients with PAD should be tailed to the clinical circumstance, lesion characteristics, and patient preference. In the future, dedicated trials directly comparing endovascular versus surgical revascularization in diabetic patients with PAD may help define optimal treatment. It is important that patients undergoing either percutaneous or surgical revascularization receive optimal secondary preventative therapy post procedure with antiplatelet and lipid-lowering agents.

Diabetes and cerebrovascular disease

The risk of stroke and transient ischemic attacks (TIA) is significantly increased in patients with diabetes [51–54]. In fact, cerebrovascular disease is the most common long-term cause of morbidity and mortality in patients with both T1 and T2DM. Since initial observations by the Framingham investigators, several large population-based studies have confirmed an increased frequency of stroke in the diabetic population [54,55]. Diabetes was the strongest single risk factor for stroke (relative risk for men 3.4 and for women 4.9) in a prospective study from Finland with a follow-up of 15 years [56]. Among stroke subtypes, diabetes is a prominent risk factor for ischemic stroke, but data on hemorrhagic stroke have been conflicting. One study suggested that the risk of stroke among patients taking hypoglycemic medications was increased threefold among the nearly 350,000 men in the Multiple Risk Factor Intervention Trial [57]. In the Baltimore-Washington Cooperative Young Stroke Study, stroke risk increased more than 10-fold in diabetic patients younger than 44 years of age, ranging as high as 23-fold in young White men [58]. Diabetes also increases stroke-related mortality, doubles the rate of recurrent stroke, and triples the frequency of stroke-related dementia [59,60].

Diabetes may also cause microatheromas in small vessels, such as the lenticulostriate arteries, leading to lacunar stroke, a common subtype of ischemic stroke. Lacunar stroke is a unique subtype and requires specific clinical and imaging features for diagnosis. Stroke patients with diabetes, or with hyperglycemia in the acute stage of stroke, have a higher mortality, worse neurologic outcome, and more severe disability than those without [61].

There is less information concerning the risk of stroke in T1 than in T2DM. The World Health Organization Multinational Study of Vascular Disease in Diabetes reported increased cerebrovascular mortality in type 1 diabetic patients however, with considerable variations between countries [62]. The data from the nationwide cohort of more than 5000 Finnish childhood-onset type 1 diabetic patients showed that, by the age of 50 years, the risk for an acute stroke was equal to that of an acute coronary event without any gender-related differences [63]. Presence of diabetic nephropathy was the strongest predictor of stroke, causing a 10-fold increase of risk. After correction for other risk factors for stroke, which are also more common in diabetic subjects, the risk still remains increased more than twofold meaning that diabetes itself is a strong independent risk factor for stroke [64].

Prevention of stroke

Measures to prevent stroke in diabetes should include a multipronged strategy targeted at treatment of hypertension, hyperlipidemia, microalbuminuria, hyperglycemia, smoking cessation, and the appropriate use of antiplatelet medication (Table 75.4).

Blood pressure

Results from the HOPE Study and Perindopril Protection Against Recurrent Stroke Study (PROGRESS) suggest that the reduction of stroke incidence in diabetic subjects during treatment based on ACE-inhibitors was greater than would be anticipated from the blood pressure-lowering effect alone and the effect was also evident in normotensive individuals [65,66]. In the Losartan Intervention For Endpoint reduction in hypertension (LIFE) study the same trend was found with an angiotensin receptor blocker, losartan [67]. However, in several other trials, including the Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), there was no apparent benefit of one class of antihypertensive drug over another in this respect [68]. Current data suggests that optimal blood pressure lowering may be more important than a particular agent.

Lipids

Treatment with statins has been shown to reduce the incidence of stroke in high-risk patients, but the diabetic subpopulations in the trials have been too small to allow a reliable subgroup analysis. In the Heart Protection Study, a sizeable subgroup of 5963 diabetic patients was randomized to placebo or 40 mg of simvastatin daily. Simvastatin reduced the incidence of stroke by a robust 24% [69].

Antiplatelet therapy

Antiplatelet therapy has also been shown to reduce the incidence of stroke in diabetic patients and is indicated for both primary and secondary prevention of stroke [70]. Aspirin in a

Table 75.4 Recommendations for prevention and treatment of stroke in diabetic patients

Recommendation	Class[a]	Level[b]
Normalization of blood pressure is recommended in all patients with diabetes for the prevention of stroke	I	A
For stroke prevention, blood pressure lowering is more important than the choice of drug Inhibition of the renin-angiotensin-aldosterone system may have additional benefits beyond blood pressure lowering *per se*	IIa	B
Inhibition of the renin-angiotensin-adlosterone system may be considered also in diabetic patients with normal blood pressure levels	IIa	B
Patients with stroke should be treated with statins according to the same principles as nondiabetic subjects with stroke	I	B
Antiplatelet therapy with aspirin is recommended for primary and secondary prevention of stroke	I	B
Patients with acute stroke and diabetes should be treated according to the same principles as stroke patients without diabetes	IIa	C
Optimization of metabolic conditions including glycemic control should be aimed for	IIa	C

low dose (75–325 mg daily) should be the drug of initial choice. In patients with recurrent stroke, a combination of aspirin and dipyridamole may be considered [71]. The alternative combination with aspirin and clopidogrel seems less safe since it was associated with an increased risk of bleeding without any benefit in terms of cardiovascular outcome in the Management of ATherothrombosis with Clopidogrel in High-risk patients with recent TIA or ischemic stroke (MATCH) Trial, performed in 7599 patients of whom 68% had diabetes [72]. In patients with atrial fibrillation, anticoagulant therapy should be given for stroke prevention.

Revascularization

The high frequency of early stroke following TIA mandates a workup within 7 days of the index event to reduce the risk of a subsequent, and potentially more serious, and even fatal neurologic event. Initial evaluation with echocardiography and carotid ultrasound is usually indicated. After a TIA or stroke caused by carotid-artery disease, medical treatments can be optimized in high-risk patients, avoiding the need for emergency carotid surgery thus allowing patients to undergo safer elective surgery [73]. Carotid endarterectomy for the prevention of stroke in patients with high-grade stenosis of the carotid artery has been shown to be effective, although it has not been specifically investigated in diabetic patients. Since complications during and after this procedure are more frequent in diabetic as compared with nondiabetic subjects, special consideration should be given to the overall risk for peri- and postoperative morbidity and mortality when deciding on surgical interventions in the patient with diabetes [74]. The presence of diabetes, however, does not seem to increase the perioperative risk of stroke [75,76]. An alternative to endarterectomy, carotid artery angioplasty and stenting (CAS), which has been found to be at least not inferior to endarterectomy, may prove to be a preferable method in high-risk patients [77] but the effects of diabetes on carotid stenting have not been well studied.

Treatment of acute stroke

The treatment in the acute phase of stroke in diabetic patients should follow the same principles that govern the treatment of stroke in the general population. Available studies have not suggested any interaction of diabetes with treatment [78]. Thrombolysis is an effective treatment for ischemic stroke if instituted within 3 hours of symptom onset. It reduces mortality and disability from stroke but is associated with a risk of hemorrhage and its use and effects in diabetes require further evaluation in clinical studies. Conservative treatment of stroke includes close surveillance of vital signs, optimization of circulation and metabolic conditions, including glycemic control, in a designated stroke unit. Patients should receive early neurologic rehabilitation with physical and occupational therapy to improve quality of life. Recent studies suggest that early intervention for hypertension during the acute phase of stroke may be beneficial but currently it is recommended to acutely reduce only very high blood pressures, above 220 mmHg systolic and/or 120 mmHg diastolic, and not lower blood pressure to levels that may enhance ischemia. Blood pressure should also not be lowered by more than 25% during the first day of treatment [79].

Conclusions

Noncoronary atherosclerotic disease such as PAD and cerebrovascular disease is a common finding in patients with diabetes. The risk of developing PAD and cerbrovascular disease is not only higher in patients with diabetes, but the disease is more severe and progresses aggressively than in nondiabetic individuals. In fact, diabetes is the most common cause of nontraumatic amputations in the United States. The major concern to patients with diabetes and PAD or cerebrovascular disease is from cardiovascular events, and the primary therapeutic goal is to modify and optimally treat atherosclerotic risk factors. Risk factor management in these individuals includes lifestyle modifications, treating associated conditions such as dyslipidemia and hypertension, and preventing ischemic events with antiplatelet therapy [81]. Pharmacologic therapies to improve symptomatic PAD include cilostazol and pentoxiphylline. A supervised exercise program should be the initial treatment step for the management of symptomatic PAD prior to starting pharmacologic therapy. Revascularization has an important role to play in the management of patients with both PAD and cerebrovascular disease for whom risk factor modification and pharmacologic treatment prove inadequate. Cardiovascular physicians should be aware of the strong association between diabetes and atherosclerosis and use appropriate medical and interventional treatments to reduce disability and death in these patients. Dedicated prospective studies are indicated to define optimal antiplatelet therapy and revascularization modality in diabetic patients.

Diabetes and public health

The diabetes challenge: from human and social rights to the empowerment of people with diabetes

C.T. Di Iorio[1], Fabrizio Carinci[1] and M. Massi Benedetti[2]

[1] Serectrix snc, Pescara, Italy

[2] Hub for International Health ReSearch HIRS, Italy

Key points

- A person with diabetes can experience a normal life.
- Discrimination still exists against people with diabetes and is widely diffused throughout the world.
- The right to enjoy the highest attainable standard of physical and mental health has still to be secured for people with diabetes.
- Strong action has been undertaken at international and local levels to protect the human and social rights of people with diabetes.
- The most relevant factor for the protection of the rights of the people with diabetes is their possibility to be an active member of their management team (empowerment).
- Empowerment can only be effective if based on solid and timely information.
- The right to accurate information is a prerequisite for the protection of human and social rights of people with diabetes.
- New technologies and methodologies have proven to be able to guarantee appropriate information in full and absolute respect of privacy.

Introduction

Diabetes is a growing "global epidemic" for which the major public health measures, including primary and secondary prevention, have basically failed to deliver the desired reduction of adverse outcomes that was globally expected.

Over 346 million people worldwide have diabetes, with a projected increase of 16% by 2025 [1]. According to the World Health Organization (WHO), 3.4 million people died in 2004 because of the consequences of high blood sugar. Unfortunately, such a threatening figure is expected to double by 2030 [2]. In economic terms, diabetes care may account for up to 15% of the national healthcare expenditure [3].

Diabetes has been defined as a "chronic, debilitating and costly disease associated with major complications that pose severe risks for families, countries and the entire world" [2]. The 2006 UN Resolution 61/225 [2] asks for "all nations to develop national policies for the prevention, care and treatment of diabetes … taking into account internationally agreed development goals, including the Millennium Development Goals." Delegates participating at the WHO 65th World Health Assembly, "approved the development of a global monitoring framework for the prevention and control of non communicable diseases (NCDs), including indicators and a set of global targets." At the same meeting, the Assembly approved a global target of a 25% reduction of deaths from NCDs by 2025.

Diabetes can play an important role in achieving such targets through an effort that will require substantial societal involvement. The diabetes challenge of the 21st century implies a shift from the "multifactorial disease approach" to a "multidimensional systemic vision" that will look simultaneously at all interrelated components. To achieve the WHO target will require a careful identification of global/national policies which must take into account all relevant environmental factors associated with the spread of the diabetes epidemic, including climate change, industry standards and consumer behavior, the health system organization and how it ensures an efficient collaboration through strategies of education and self-care.

At the same time, achieving targets in diabetes will need the active participation of people with diabetes.

The notion of empowerment is a relatively new element of a multifaceted strategy that has been recently embraced even at the highest political level [4]. It advocates the direct involvement of individuals in shared processes, by respecting human, social and health rights, with a continuous provision of accurate information and educational tools for disease management.

According to the International Diabetes Federation (IDF), people with diabetes should live their lives as normally as possible. Only through the elimination of current barriers, they will be able to play an active and equal role in society, aware of the risk of major complications that could lead to disability, reduced quality of life, and death [5].

To guarantee the right to health to people living with diabetes, adequate consideration should also be given to all disabilities directly associated with the progression of the disease.

In this chapter, we provide an overview of the legal background and international instruments available to empower people with diabetes from a comprehensive perspective.

First, we present the fundamentals of the right to health through an overview of international treaties. Since 1948, many legislative instruments have been enacted at a global level, particularly by the United Nations (UN) and the European Union (EU).

The following section introduces the human and social rights of people with diabetes and provides details of the IDF International Charter of Rights and Responsibilities, which solemnly declares the current trend to enhance the role and responsibilities of individual subjects in the global fight against the disease.

The section "Rights and responsibilities on diabetes information and education" analyzes how such roles can be played in the context of the individual right to education and information, as required for the proper management of diabetes. The discussion herein aims to demonstrate that the adoption of a comprehensive notion of empowerment is currently recognized by the international instruments.

Finally, we envisage ways to implement such a comprehensive concept of empowerment. Strengthened healthcare systems require a deep understanding of the links between actions and different environmental factors. The case of interconnected diabetes registers is presented as a practical solution that could realize this vision and help meeting the ambitious targets recently set by the WHO.

The right to health

The right to health is enshrined in numerous international and regional human rights treaties. The 1948 UN Universal Declaration of Human Rights (Art. 25) first recognized that every human being has "*the right to a standard of living adequate for the health and well-being of himself and of his family, including food, clothing, housing and medical care and necessary social services*" [6]. However, the Declaration had no binding force until 1976, when the International Covenant on Civil and Political Rights (ICCPR) and the International Covenant on Economic, Social and Cultural Rights (ICESCR) became international law. The Universal Declaration of Human Rights, together with these two covenants, constitutes the so-called "International Bill of Human Rights."

Article 12 of the International Covenant on Economic, Social and Cultural Rights (1966) [7] specifically "*recognize*[s] *the right of everyone to the enjoyment of the highest attainable standard of physical and mental health*," which includes an obligation on States Parties to take the necessary steps to fully realize the right to health.

The 2000 UN General Comment No.14 "Right to Health" [8] specifies that although Article 12 of the Covenant did not adopt the definition of health contained in the preamble to the Constitution of WHO, which envisages health as "*a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity*," the reference in Article 12.1 of the Covenant to "*the highest attainable standard of physical and mental health*" has to be broadly interpreted. It means that the right to health should not be limited to the right to healthcare, but should extend to the underlying socioeconomic determinants of health, for example access to safe and potable water, adequate sanitation, adequate supply of safe food, nutrition, housing, healthy occupational and environmental conditions, access to health-related education and information on a range of topics, for example sexual and reproductive health. According to the General Comment, the right to health is composed of four elements: availability, accessibility, acceptability, and quality. Availability refers to the provision of sufficient public health and healthcare facilities, programs, goods and services. Accessibility is composed of four dimensions: nondiscrimination, physical accessibility, economical accessibility (affordability), and information accessibility. Acceptability implies that health facilities, goods and services must respect ethical principles. Quality means that health facilities, goods and services must be scientifically and medically sound.

The right to health has been also recognized in the following treaties: the 1965 International Convention on the Elimination of All Forms of Racial Discrimination [9], the 1979 Convention on the Elimination of All Forms of Discrimination against Women [10], and the 1989 Convention on the Rights of the Child [11].

At regional level, several human rights instruments also recognize the right to health.

In the EU, two international legal instruments play a crucial role in the recognition and affirmation of the right to health: the European Social Charter and the EU Charter of Fundamental Rights. The 1996 revised European Social Charter [12], which operates through international law, is binding for all signatory States, including all EU Member States (MS). Article 11 of the Charter proclaims the right to the protection of health and poses on Contracting Parties an obligation to take the necessary steps "*to remove as far as possible the causes of ill-health; to provide advisory and educational facilities for the promotion of health and the encouragement of individual responsibility in matters of health; and to prevent as far as possible epidemic, endemic and other diseases as well as accidents*." The European Committee of Social Rights specified that the right to health includes

the following components: ensuring an adequate healthcare system, access to health and healthcare for vulnerable groups, public health protection measures (e.g. preventing air and water pollution, noise abatement, food control, and environmental hygiene) and providing health education [13].

The EU Charter of Fundamental Rights [14] can be considered a major development in the EU agenda for human rights. The Charter has been incorporated in the Lisbon Treaty, which entered into force in 2009. As a consequence of the entry into force of the Lisbon Treaty, the Charter gained the same legal value as the EU Treaties. The catalogue of civil, political, economic and social rights enshrined in the Charter is currently legally binding for all MS, with regard to the implementation of Union law, and enforceable through the Court of Justice. The Charter expands the scope and recognition of fundamental rights, for example dignity, freedom, equality, solidarity, citizenship and justice, to the proclamation of additional rights such as data protection, bioethics, and the right to good administration. Article 35 of the Charter specifically deals with healthcare: "*Everyone has the right of access to preventive health care and the right to benefit from medical treatment under the conditions established by national laws and practices. A high level of human health protection shall be ensured in the definition and implementation of all Union policies and activities.*"

In the African Region, the 1981 African Charter on Human and Peoples' Rights [15], which entered into force in 1986, recognizes the right to health in Article 16, which states that "*every individual shall have the right to enjoy the best attainable state of physical and mental health. States parties to the present Charter shall take the necessary measures to protect the health of their people and to ensure that they receive medical attention when they are sick.*"

Article 10 of the 1988 Additional Protocol to the American Convention on Human Rights [16] in the Area of Economic, Social and Cultural Rights (the Protocol of San Salvador) adopts the wording of the WHO Constitution, defining the right to health as "*the enjoyment of the highest level of physical, mental and social well-being,*" which has to be considered as a "*social good.*" Among measures ensuring the right to health, States Parties shall guarantee: primary healthcare; extension of the benefits of health services to all individuals subject to the State's jurisdiction; universal immunization against the principal infectious diseases; prevention and treatment of endemic, occupational and other diseases; education of the population on the prevention and treatment of health problems, and satisfaction of the health needs of the highest risk groups and of those whose poverty makes them the most vulnerable.

Considering the above-mentioned international instruments it can be highlighted that the notion of right to health is globally conceived as inclusive of all the socioeconomic and environmental determinants of health and expands to various dimensions that are strictly dependent upon the realization of other fundamental human and social rights. As a matter of fact,

the right to food, housing, work, education, human dignity, life, nondiscrimination, equality, the prohibition against torture, privacy, access to information, freedom of association, assembly and movement are strictly interlinked with the right to health and play a crucial role for achieving the highest attainable standard of health for all.

Human and social rights of people with diabetes

Diabetes is a chronic potentially debilitating disease leading to major complications as the disease progresses. Targeted measures and policies are needed to ensure that people with diabetes may enjoy their lives even in the face of significant hurdles.

The interdependence between the right to health and the other human and social rights is evident in the unfortunate occurrence of disability, where the respect of the principle of nondiscrimination is key to ensuring the highest attainable standard of health.

Many regional legislative instruments deal with persons with disabilities. The revised European Social Charter [12] states that persons with disabilities have the right to independence, social integration and participation in the life of the community (Art. 15); and States Parties have to undertake specific steps to ensure the effective exercise of this right. Article 26 of the EU Charter of Fundamental Rights [14] disciplines the integration of persons with disabilities, recognizing that they have to "*benefit from measures designed to ensure their independence, social and occupational integration and participation in the life of the community.*" The 1981 African Charter on Human and Peoples' Rights (Art. 18) [15] specifies that "*the aged and the disabled shall also have the right to special measures of protection in keeping with their physical or moral needs.*" Article 10 of the 1988 Additional Protocol to the American Convention on Human Rights in the Area of Economic, Social and Cultural Rights (the Protocol of San Salvador) [16] provides "*protection of the handicapped*" by asserting that "*everyone affected by a diminution of his physical or mental capacities is entitled to receive special attention designed to help him achieve the greatest possible development of his personality. The States Parties agree to adopt such measures as may be necessary for this purpose.*"

Building upon previous legislative instruments, the UN General Assembly adopted the Convention on the Rights of Persons with Disabilities [17] in 2006. The Convention on the Rights of Persons with Disabilities and its Optional Protocol can be considered as a human rights instrument that provides explicit social development goals.

The Convention adopts a broad and evolving concept of disability. In particular, disability "*results from the interaction between persons with impairments and attitudinal and environmental barriers that hinders their full and effective participation in society on an equal basis with others.*"

It defines in detail the rights of people with disabilities and provides specific ways of implementation. Accordingly, States Parties have to guarantee a series of specific rights to persons with disabilities, spanning from the right to life on an equal basis with others, to the right to nondiscrimination, legal and social protection, privacy, education, work and health, including comprehensive habilitation and rehabilitation services in the areas of health, employment and education. Article 25 of the Convention deals with disabilities in relation to the attainment of the right to health, specifying that "*persons with disabilities have the right to the enjoyment of the highest attainable standard of health without discrimination on the basis of disability.*"

According to Article 4, ratifying countries have to develop and implement policies, laws and administrative measures that ensure the fulfillment of the rights recognized by the Convention and repel incompatible laws/regulations. Among possible approaches to implementation, Article 8 also promotes a change in perceptions of disabled people, by increasing awareness of their capabilities and combating stereotypes and prejudices.

Finally, Articles 33–39 provide monitoring mechanisms to regularly assess progress in the implementation of the Convention.

Building upon fundamental human rights instruments, for example the Convention on the Rights of the Child (CRC), the Convention on the Elimination of All Forms of Discrimination against Women (CEDAW) and, above all, the Convention on the Rights of Persons with Disabilities, the IDF has developed the International Charter of Rights and Responsibilities of People with Diabetes [18]. The vision of the Charter is to "*optimize health and quality of life, enable people with diabetes to have as normal a life as possible, reduce or eliminate the barriers which deny realization of full potential as members of society.*"

The Charter specifies the fundamental human and social rights of people living with diabetes, providing specific examples regarding the right to healthcare, information, education, and social justice, while at the same time recognizing their own responsibilities. Therefore, the Charter aims to guarantee the rights and freedoms of people living with diabetes, to combat the discrimination and stigma that they often face under such condition, and, at the same time, to foster their empowerment.

In particular, the right to care includes the following: to have an early diagnosis and affordable and equitable access to care and treatment; to receive regular, reliable advice, education and treatment in accordance with evidence-based practices; to benefit from proactive health sector community outreach, education and prevention campaigns in every healthcare setting; to access high-quality services and care during and after pregnancy and childbirth, during childhood and adolescence; to keep information related to their disease confidential and in accordance with privacy and data protection principles and to receive continuous and appropriate care in cases of disaster and emergency.

The right to information and education spans from the prevention, detection, management and access to educational resources, to the training in self-management, the direct involvement (together with healthcare organizations) in the planning of health goals, obtaining information on interventions (including risks and benefits), and access to medical records.

The right to social justice implies that people with diabetes shall be considered as fully engaged members of the society, who can access medication and monitoring technologies, are not discriminated against in accessing insurances and a driving license, are fairly treated in employment and career progression, and are duly supported in social and school/work environments.

Finally, people with diabetes have the responsibility to share all relevant information with healthcare providers, be able to manage their agreed care and treatment plan, implement healthy lifestyle behaviors as part of their self-management, inform family, school/work/social colleagues of their condition and be respectful of the rights of others with diabetes.

The Charter finally urges the international community to apply the principles therein contained, through national plans for diabetes care, prevention, research and education, while ensuring a regular monitoring and review of the Charter's status of implementation.

Although the Charter is not legally binding for the international community, nevertheless it shall be regarded as an international declaration that can be used as a powerful campaign instrument to help counteract the diabetes epidemic through a global concerted action.

Rights and responsibilities on diabetes information and education

As early as 1989, the St. Vincent Declaration [19] recognized that reducing the burden of diabetes could only be achieved through an active partnership between people with diabetes and service providers, particularly in the areas of disease management and education.

This assumption advocates the fundamental principles of patient empowerment, a concept that after two decades has become broadly used in the field of healthcare. Empowerment has been defined as "the ability of a person affected by a disease to be an active member of his/her management team" [20]. It addresses different dimensions of care management, for example the ability of a person to make decisions on treatments, education on both medical and health conditions, as well as consciousness of the emotional impact of the disease. Patient empowerment integrates multiple concepts allowing a person to effectively self-manage her/his disease [21]. To make this possible, patients have to be involved and educated on the application of multiple concepts. In diabetes, patient empowerment translates into improving adherence to agreed self-care regimens. Expected outcomes may include certain elements, for example weight loss, maintaining normal blood glucose levels, and the prevention of complications [22]. Chronic disease self-management programs, which strongly rely on

self-management education, have been tested in randomized controlled trials, showing significant improvements in the areas of healthy behaviors, communication with healthcare providers, health status and, most importantly, optimal use of healthcare [20].

Consistently with the available evidence, the International Charter of Rights and Responsibilities of People with Diabetes [18] aims at elevating the notion of patient empowerment to the status of a social right by according people with diabetes the right to information and education.

In particular, people with diabetes have the right to:

- receive the highest level of information and high-quality education about diabetes, including prevention and early detection strategies, particularly in high-risk individuals;
- gain knowledge on how the disease can be managed effectively and how to access education and clinical resources; be trained in self-management from the diagnosis onward, integrating the clinical, behavioral and psychosocial aspects of diabetes, either as a group or on an individual basis; be involved in assessing, planning, implementing, and routinely monitoring own care and health goals;
- access reliable information about the names and dosage of any relevant therapy/medication, including their action and potential side effects, as well as the interactions with other medical conditions and therapies, specific to the individual; share own information with care providers and access own medical records and other relevant information if explicitly requested.

On the other hand, the Charter states that people with diabetes have responsibility to:

- share information with their healthcare providers on their current state of health, which types of medicines they are using, any relevant allergies, social/lifestyle behaviors or other information that would be relevant for clinical decision making and expert advice;
- manage their agreed care and treatment plan;
- adopt, implement and monitor healthy lifestyle behaviors as part of their self-management of diabetes;
- share any problems they experience with their healthcare providers, including treatment plans and any barriers to their successful implementation;
- inform family, school, work and social colleagues of their disease condition, so that they can be supportive whenever needed;
- show consideration and respect for the rights of other people with diabetes and their healthcare providers.

The Charter considers people empowerment as a crucial aspect to combat the diabetes epidemic and its negative consequences.

Consistently with other aspects of modern society, the availability of timely information is crucial to control the effects of multiple factors under changing conditions. In the epidemiology of diabetes, it is important to simultaneously consider the impact of evolving scenarios in diverse areas that are not always immediately actionable, for example climate change, rapid change of environment, employment status, health system reform, healthcare settings, and socioeconomic determinants of health. Patient empowerment assigns to people with diabetes the task of actively improving the quality of their own healthcare, through difficult evaluation strategies that may include benchmarking own results against those obtained by other healthcare providers under similar conditions. Though compelling, this concept may not be easy to apply for all subjects.

The challenge extends to modern health information systems: empowered patients need comparable information, which is seldom available in a standardized format—particularly at the international level—and is rarely customized to respond to the needs of a specific category of users.

Diabetes represents an almost perfect model for analytical purposes, with its multiple dimensions and well-defined data structures. For this reason, diabetes has been defined as a data-driven disease which allows information to be effectively linked for multiple purposes [23]. During recent years, diabetes registers have been increasingly regarded as a comprehensive solution to collect reliable data and derive indicators of quality of care and outcomes, allowing an active use of health information by different categories of users [24].

The EU has closely followed these developments in recent policy statements. In 2006, the EU Conclusions on the promotion of healthy lifestyles and prevention of type 2 diabetes [25] urged Member States "*to foster the collection, registration, monitoring and reporting at national level of comprehensive diabetes epidemiological and economic data as well as data on the underlying factors*"; and to implement "*evaluation systems with measurable targets to track health outcomes and cost-effectiveness, taking into account Member States' organization and delivery of their respective health services …* ".

At the same time, the European Commission committed to support the "*networking and the exchange of information between Member States with a view to promoting best practice, reducing inequalities and optimizing healthcare resources; and examine and strengthen the comparability of diabetes epidemiological evidence by considering the establishment of standardized outputs for monitoring, surveillance and reporting of diabetes mortality, morbidity and risk factor data across Member States.*"

The above concepts attained the highest degree of recognition in the EU Parliament resolution of 14 March 2012 on addressing the EU diabetes epidemic [26], which basically confirmed all the above statements on the necessity of a systematic data collection and monitoring of diabetes complications and health outcomes across Europe.

The implementation of efficient solutions for strengthening healthcare systems represents today a specific responsibility for policy makers and healthcare providers and a means to ensure the highest attainable level of health for people with diabetes. Through the different legislative instruments passed in recent years, and, above all, the International Charter of Rights and Responsibilities of People with Diabetes, patient empowerment and the right to health information have left the domain of

academic investigation to become an integral component of the societal strategy against the rising burden of diabetes.

Conclusion: the way forward

Nowadays, the role of people with diabetes should be considered as central in a complex interrelated network of political, social, and economic interests. The subtle implications of such a scenario need to be fully recognized and properly managed to improve the strategy to protect the right to health of people with or at risk of diabetes.

The diagram presented in Figure 76.1 represents the person with diabetes within a comprehensive perspective of mutual interaction.

People with diabetes stand at the top of a "pyramid of empowerment" composed of blocks of human actions, organized to respond to problems that originate from a series of connected domains (nested circles).

The foundations of the pyramid are laid by laws, regulations, and international charters which are continuously updated to support the life of people with diabetes within a changing environment, to ensure the respect of social values and human rights. The social and natural environment directly influences the adoption of public health measures, for example prevention policies and health promotion campaigns, whose content is based on the evidence produced by research, which in turn provides the basis for the preparation of clinical guidelines. The availability of guidelines ensures the provision of appropriate

health services and regulates the market for medical devices and products, within a broader context of health systems that can be organized in different ways (e.g. universal coverage vs. private insurance). Effective solutions for the prevention of diabetes complications, for example integrated disease management, may be variously organized and supported by powerful technology.

As for many other aspects of modern society, being able to manage own rights strictly depends on the competent use of all information flowing across the different levels of the pyramid. Citizens must be able to evaluate their condition in a broader scenario, where each element contributes to the general conditions of social policy and healthcare.

Using medical records effectively is essential to close the loop of the empowerment cycle, but such capacity is limited by the ability of the system to integrate all sources and produce information that can be easily interpreted by anyone (e.g. health indicators). This requires the implementation of automated procedures that can provide access to updated population data in real time, through systematic and efficient health information systems.

In general, apart from basic indicators of limited interest (e.g. diabetes prevalence), the personal use of comparable health information is yet to be realized. However, recent developments in the field of disease registries, organized on top of routine records of episodes of care that are stored for different reasons (e.g. quality of care and expenditure control in diabetes, hypertension, and renal disease), could pave the way forward. Although the situation is rapidly improving, registries have often been developed only for well-resourced settings rather than entire populations, for which ad hoc surveys are still the solution of choice [27].

In a field such as diabetes, for example, where data is abundant but information is still scarce, population-based registers may represent a pragmatic solution connecting the interests of people with diabetes to those of public health intelligence [28]. Registers are population-based when they are structured in a way that results for a specific category of subjects (e.g. people with diabetes) can be compared against those of the general population, through denominators that are usually determined by storing a complete master index for a defined geographical area. This is evidently possible only if the public service itself, for obvious legal implications, is supervising the entire process, rather than the traditional organization of surveillance registries, for example cancer registries, where research institutions are at the heart of the entire process. Population-based registers, particularly those organized at a regional level, are usually intrinsic to the process of care and are aimed to deliver much more than the basics of producing public health indicators.

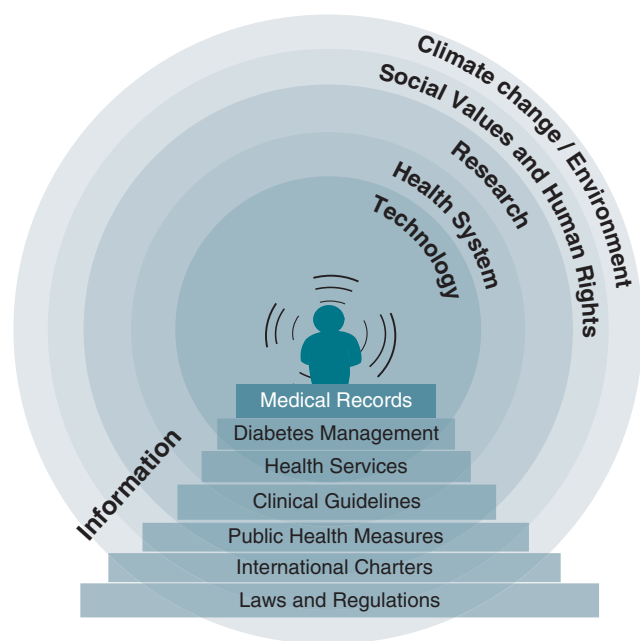
In the near future, modern forms of information delivery will serve the interest of people with diabetes more closely, through services such as robust and timely information on the epidemiology of diabetes and its complications; evaluation of


Figure 76.1 The pyramid of empowerment of people with diabetes.

quality of care and interventions in a changing environment; estimates of the cost of the disease; interfaces for shared care and self-management; flags for high-risk subgroups of individuals; levels of adherence to treatment guidelines; data extraction for diabetes research.

To become a strategic element for the improvement of health outcomes [29], such information shall be open to everybody: national and local decision makers, healthcare administrators, health professionals, research institutions, and all citizens.

A practical example of a diabetes information system that operates consistently with the whole framework presented here has been realized by two sequential EU projects: "Best Information through Regional Outcomes" (BIRO) [30] and "European Best Information through Regional Outcomes in Diabetes" (EUBIROD) [31].

The BIRO [32] system implemented an open source architecture, based on the concept of "privacy by design," which allows the cross-border flow of information across diabetes registers in Europe. The system is structured on a data model that regards each element (a regional/national government, the single care provider, or even a person with the disease) as a potential data source contributor. The same software, including advanced statistical routines, runs safely on the database stored at each node, using a predefined set of standardized criteria. Only aggregate data are transmitted to produce the pooled results. As the system is general, it delivers a wide range of quality and outcome diabetes indicators, compiled into a final common report template that can be used to inform all the above-mentioned categories of users.

The EUBIROD project delivered results obtained through the application of the BIRO information system in 20 countries, including demographics, clinical characteristics, risk factors, health system structures and processes, population rates, and risk-adjusted estimates of intermediate/terminal outcomes. EUBIROD also delivered an interface through which each data source can independently assess the level of adoption of privacy and data protection principles, including issues of data quality and access rights ("privacy performance assessment") [33].

Novel approaches, for example those successfully applied in EUBIROD, undoubtedly show that there is enormous potential, at limited cost, still waiting to be exploited. Moving from prototypes to permanent systems will allow strengthening of the level of participation of the entire community, empowering each individual through direct access to relevant data and the independent assessment of trusted sources of information. This way, each person will be able to assess, discuss or dispute the accuracy of medical records, and use this information to set up eventual complaint procedures. The availability of all these elements will be equally crucial for ensuring the empowerment of people with diabetes.

Diabetes population-based registries, when based on an efficient information system, could represent a solid tool to ensure the right to health for people with diabetes: a right conceived as a comprehensive and multidimensional concept encompassing all relevant human and social rights, as well as the empowerment of people with diabetes.

CHAPTER 77

The economics of diabetes care: a global perspective

Rhys Williams
Swansea University, Swansea, UK

Key points

- Increases in the prevalence and economic impact of diabetes have resulted in greater perceived importance and availability of good quality information on the economics of diabetes and diabetes care.
- Information is available which quantifies the substantial economic impact of diabetes on individuals, families, healthcare systems, and society. These descriptive studies have used a variety of methods.
- Analytical studies have identified interventions in primary prevention, early detection by screening and treatment of established diabetes which, when compared with current alternatives, are "cost saving" or "very cost effective."
- Much of this evidence relates to developed countries despite the fact that 80% of the estimated 366 million people with diabetes live in low- and middle-income countries, which have particularly severe constraints on healthcare resources.
- Further work in this area needs to continue to inform clinicians and health policy makers so that scarce resources can be used efficiently to reduce the impact of diabetes and improve the quality of life of those who live with the condition.

- The current emphasis on evidence-based practice in healthcare and the acceptance that evidence on efficiency (i.e., the best use of resources) must be combined with evidence on effectiveness;
- The plethora of new interventions, not only for the management of diabetes but also for its primary prevention;
- The worldwide severe constraints on resources, not only for healthcare but for all activities of human communities.

The scope of this chapter

This chapter reviews some of the evidence that has accumulated, since the publication of the previous edition, on the economic impact of diabetes and on the cost effectiveness of interventions. It aims to provide clinicians and health policy makers with information on the economic impact of diabetes and an indication of how diabetes management and service development should evolve in relation to economic considerations. It does not claim to be a systematic review in the sense used, for example, by the Cochrane Collaboration but recently published studies have been selected if they are considered to contribute significantly to these aims. Given the need to restrict its length, the chapter cannot claim to be a comprehensive review of this burgeoning field.

Two literature searches (details available on request) were employed for this chapter. Search number 1 was highly sensitive with a wide range of economic terms. It yielded over 37,000 potentially relevant titles. Search number 2 was more specific and orientated more towards analytical studies. It yielded 850 potentially relevant titles. The remainder of the chapter is divided into two broad areas: studies of the economic impact of diabetes; and studies of the cost effectiveness or cost utility of interventions. Since the primary prevention of diabetes (or a significant delay in its onset) is the intervention likely to have the greatest reduction in its economic impact and since the evidence for the preventability of T2DM is now overwhelming, primary prevention is included in the term "diabetes care."

Introduction

In the 20 years since the first appearance of the *International Textbook of Diabetes Mellitus* [1] the perceived importance and availability of good quality information on the economics of diabetes and diabetes care have increased dramatically. Reasons for this were expounded by Songer and Barceló [2] in the previous (third) edition of this textbook. Revisiting and updating these reasons suggest that the following are among the most significant:

- The dramatically increasing prevalence of T2DM and diabetic complications worldwide but, in particular, in the developing world;
- The realization that this poses a substantial threat not only to the welfare of individuals and families but to national economies and economic stability and growth;

The global literature now convincingly demonstrates that diabetes has considerable economic impact but that many interventions to prevent or delay its onset and to prevent or delay its complications are cost effective or even cost saving. However, the overwhelming majority of this evidence relates to developed (high-income) countries. A significant challenge now is to explore in much more detail the economic features of interventions in low- and middle-income countries — the location of much of the explosion in T2DM diabetes incidence and prevalence.

The economic impact of diabetes

Estimates of costs—from different perspectives

Fundamental to the quantification of the economic impact of any condition is the question of viewpoint, that is, when costs are being identified, is this from the point of view of the individual with the condition, that of the family, the health system, society as a whole, or a combination of these? The most comprehensive, recent information on diabetes healthcare expenditures is that published by the International Diabetes Federation (IDF) [3]. These data are estimates of healthcare expenditures by country which include spending by health systems as well as by individuals or families living with diabetes. The proportions attributable to systems on the one hand and to individuals on the other will vary from country to country according to the funding arrangements for the delivery of care.

Using formulae first put forward by Jönsson [4], the method used requires knowledge of the prevalence of diabetes, the total healthcare budget of each country, and an assumption of the ratio of the total cost of medical care for people with diabetes compared to the cost of care for people without diabetes — the "diabetes cost ratio" (R). These formulae enable the calculation of the total cost of care for people with diabetes (i.e., including costs both directly attributable to diabetes plus the costs of other care) and the costs specific to diabetes. Initial estimates of these costs [5] and the most recent estimates [3] have assumed likely lower and upper bounds of R of 2 and 3.

In 2011 an estimated USD 465 billion was spent worldwide in treating diabetes and preventing its complications [3]. Such a sum is difficult to comprehend in isolation. More meaningful, perhaps, is that this amounts to 11% of the world's total health expenditure and that, per person with diabetes, the average annual expenditure is USD 1274. As will be emphasized later, this average figure conceals gross disparities in the resources available for diabetes care in different countries (and, quite plausibly, within countries). An estimated 20% of global diabetes expenditure is attributable to low- and middle-income countries in which 80% of people with diabetes live [3]. In high-income countries (such as the USA, UK, Japan, etc.) the average per person annual expenditure is USD 5063 compared with USD 271 in low- and middle-income countries. Conversion of these sums to International Dollars (ID) (thereby correcting for national differences in purchasing power) reduces this difference slightly — to ID 4888 compared with ID 456 — but by no means eliminates it. Perhaps the most chastening figure of all is the estimate that, in 2011, the USA accounted for 43% (USD 201 billion) of the world's expenditure on diabetes, this sum being spent on a mere 6.5% of the world's diabetic community [3].

Estimating diabetes healthcare expenditure using such formulae is a "top-down" approach, that is, calculating expenditures on individuals using epidemiologic and financial data from populations. These IDF estimates do not differentiate between T1 and T2DM; however, for most countries, the bulk of these expenditures will be attributable to the latter. Differentiation of expenditures according to diabetes type is possible by this method given data for the prevalences of T1 and T2DM separately, but the diabetes cost ratio is likely to be significantly different for the two subtypes driven mainly by the different age profiles of the type 1 and type 2 populations. In most populations, hospital admission is the main driver of expenditures and it has long been known that, although the absolute incidence of hospital admission is greatest in the elderly, the greatest relative difference in admissions between individuals with diabetes and those without is seen in the young. Thus, the diabetes cost ratio for T1DM, in locations where diagnosis is possible and treatment is accessible, will be greater than that for T2DM.

A recent, detailed study which has used an alternative (and more commonly used) top-down approach to estimate T1 and T2DM costs separately is that of Hex et al. [6]. This used aggregated, routinely available data (on hospital admissions, prescriptions and primary care consultations, for example) and estimates (of premature mortality, for example) from the epidemiologic literature to quantify cost of T1 and T2DM separately in the UK in 2010/2011 and to predict what these costs are likely to be in 2035/2036. They considered both direct healthcare costs and indirect costs (i.e., the wider costs attributable to diabetes outside the realm of healthcare). In the former category were the costs of screening and testing (for diagnosis and retinopathy), those attributable to treatment and management of diabetes itself, and those attributed to treating its complications. Included in the indirect cost total were estimates for loss of productivity due to premature mortality, informal care, sickness absence (absenteeism) from work, and the potential loss of productivity among people with diabetes who remain at work (so called "presenteeism" [7]). The main features of their findings are summarized in Table 77.1. Even though these estimates relate specifically to the UK context, they illustrate a number of important features which will be applicable to other contexts.

First, Hex and coworkers's estimate of indirect costs for both forms of diabetes combined exceeds those for direct costs (58.6% of costs vs. 41.4% in 2010/2011 and 57.5% vs. 42.5% in 2035/36) [6]. Thus, even though the economic impact of diabetes on healthcare is high, its impact outside the realm of healthcare is higher still. This finding in the literature is common though not universal (see, for example, reference [8]).

Table 77.1 Estimates of the economic burden of diabetes in the UK for 2010/2011 and projections to 2035/2036

Costs		2010/2011			2035/2036		
		All diabetes	Type 1 diabetes	Type 2 diabetes	All diabetes	Type 1 diabetes	Type 2 diabetes

[a]Proportion of direct costs for that type of diabetes at that time.
[b]Proportion of all costs for that type of diabetes at that time.
[c]Proportion of indirect costs for that type of diabetes at that time.
*£1 ≈ USD 1.58
Source: Adapted from Hex 2012 [6].

Second, the predominant factor in direct costs is complications (via hospitalizations) accounting for between 70% and 80% of direct costs. Within this subcategory of complications (not shown in Table 77.1), the costs of renal failure and foot ulcers and amputations are the two largest clearly defined categories (although exceeded by "other cardiovascular disease") accounting for, in 2010/2011, around one third of complication costs. Within this subcategory Hex et al. [6] have included an estimate for "excess inpatient days" on the assumption that a person with diabetes as a comorbid condition occupies a hospital bed for 2.6 days more than a similar person without diabetes for routine surgery [9]. This might be designated an "indirect, direct cost."

In the category of indirect costs, the costs of loss of production from premature mortality predominate, accounting for, in 2010/2011, two thirds of indirect costs in T1DM and one third in T2DM. The costs of informal care are also substantial (17.1% and 38.3% of the 2010/2011 indirect costs in T1 and T2DM, respectively). Though not often costed in any detail, these aspects of care have long been known to be significant (e.g. see reference [10]) with contributions both in terms of the affected person and their relatives. Hex and coworkers' estimates for "presenteeism" are equal, in proportional terms, to that for absenteeism in T1 but greatly exceed those for absenteeism in T2DM. The authors are clear that the methods for estimating the costs of presenteeism are in their infancy [6]. Nevertheless, these estimates are bound to be contentious since they imply that people with diabetes in work are considerably less productive than they should be, because of their diabetes.

Hex and coworkers' predictions for costs in 2035/2036 make use of population projections and plausible assumptions about changes in prevalence and outcomes. Within the direct care category, the proportional contributions of the subcategories do not change greatly. However, within the indirect cost category, the proportional contributions of premature mortality costs are expected to fall (which is gratifying) whereas those of informal caring are expected to rise—which is more concerning. As might be expected, costs rise in all categories, driven by higher prevalences, higher treatment costs, and higher costs of complications. The total cost of diabetes (direct and indirect, type 1 and type 2) is predicted to rise by 68% on its 2010/2011 total while the rise for type 1 and type 2 separately are 121% and 63%, respectively [6]. The predicted increases in direct and indirect costs are roughly equal whereas the predicted increase of indirect costs for type 1 is, in proportional terms, the largest of all. The authors comment that "any improvements in the way diabetes is treated that lead to better glycemic control and fewer complications could have a significant impact on these costs, but this remains to be assessed." To this should be added that reduction in prevalence through primary prevention would be expected to contribute significantly and that the goals of treatment should be widened to include other important parameters such as blood pressure and lipids. The authors' comment about the need to take into account improvements in outcome is particularly pertinent given the observations being made in many high-income countries that the excess mortality resulting from diabetes is declining and that, as part of this, age-specific mortality from cardiovascular disease has decreased more in people with diabetes than in their nondiabetic peers. These changes and concomitant improvements in morbidities such as visual and renal impairment will need to be taken into account in revisions of models such as that of Hex et al. [6].

The bottom-up approach, that is, gathering data on individual expenditures and collating them to determine population-level costs, also enables estimates to be made specifically for T1 or T2DM without the need for diabetes cost ratio assumptions. A bottom-up approach is being used in the 3C Study [11] which aims to describe coverage, cost, and care of T1DM in the Beijing and Shantou regions of China. The sampling unit is the individual with T1DM recruited from the outpatient and inpatient records of hospitals in the two regions. Interviews with participants, data from hospital billing departments, medical records departments, and government sources are being used in a combination of bottom-up and top-down approaches to calculate direct medical costs, direct nonmedical costs and indirect costs from different viewpoints—patients and their families, health system, insurers, and the wider society. This and other ongoing studies as yet unpublished may well confirm that the diabetes cost ratio, at least in some populations, is significantly greater than the 3 previously taken as the likely upper limit.

The evidence base for the costs of diabetes in countries other than the Americas, western Europe and Australasia is growing (see, for example, data from India [12,13], Ethiopia [14], and Iran [15]). However, Grover et al. [12] comment that "the data regarding cost of care of diabetes mellitus from developing countries are scarce." A weakness of a number of these studies currently is that some are based on small samples of participants attending one (or a few) healthcare settings (e.g. [12,14]). Studies based on larger samples, preferably community based (e.g. [13,15]) are needed. Feleke et al. [14], however, and Esteghamati et al. [15] have the strength of nondiabetic participant data sampled from the same source.

Drivers of direct costs

Given that hospital admission for diabetes is an important driver of healthcare expenditures and that the bulk of hospital admissions of people with diabetes are for the treatment of complications, it follows that the presence of complications will be a potent influence on healthcare costs. Many studies have confirmed this.

The CODE-2 (Cost of Diabetes in Europe – Type 2) study [16] applied the same (bottom-up) methodology in eight European countries and demonstrated that the average healthcare cost per patient was 3.5 times greater in those with both micro- and macrovascular complications compared with those with no recorded complications. The presence of microvascular complications alone increased the per person costs by a factor of 1.7 and that of macrovascular complications alone doubled them. The presence of both types of complications increased costs specific to hospitalization by 5.5 times that found in the comparison group.

Since the publication of CODE-2, other studies have confirmed these findings. For example, the CODEIRE study (in the Republic of Ireland) [17] found that the presence of both micro- and macrovascular complications increased the annual cost of care by a factor of 3.8 compared to people with diabetes but with no complications; microvascular complications alone and macrovascular complications alone were associated with increases of 1.8 and 2.9, respectively. Morsanutto et al. [18] found that the presence of more than two diabetic complications increased the per person annual healthcare costs by a factor of 3 in their study of patients attending the diabetes centre of Portogruaro, northern Italy. More recently, Clarke et al. [19], using a different method, quantified the costs of diabetic complications in Western Australia. Their estimates for the costs of seven common complications—renal failure, lower limb amputation, heart failure, chronic leg ulcer, nonfatal stroke, ischemic heart disease, and nonfatal myocardial infarction—ranked in that order with the average costs in the year the event first occurred to a 60-year-old man ranging from AUD 28,661 (95% CI 22,989–34,202) for renal failure to AUD 11,660 (95% CI 10,931–12,450) for a nonfatal myocardial infarction (1 AUD ≈ 1.04 USD).

When individuals and families pay the cost of care themselves

The economic impact of diabetes can be particularly savage when much or most of it is borne by individuals or families. A larger share of healthcare expenditure for the condition is shouldered by individuals living in low- and middle-income countries when compared with those living in high-income countries [3]. In Latin America, for example, 40–60% of the cost of medical care for people with diabetes is out-of-pocket (i.e. financed from personal income) [20].

At least one study from India [21] has reported an increase over time in the extent to which families living with diabetes have to use their own income to fund diabetes care. Information from a sample of patients attending hospital clinics and general practitioners in urban and rural areas of seven states in India in 2005 showed that families in urban areas spent, on average, 10% of their income funding the care of a diabetic member while, for families in rural areas, the figure was 17%. Compared with a previous, similar study carried out in 1998 [22] and after accounting for inflation, the proportion of family income devoted to diabetes care had increased by 113%. In both studies, poorer families contributed larger proportions of their income than did the wealthier families and the secular increase was most marked in the poorest families increasing from 24.5% in 1998 to 34% in 2004.

Sharing some of the characteristics of the poor in low- and middle-income countries are the uninsured and underinsured of the USA. A recent study of coverage for people with diabetes [23] compared health insurance coverage and type of coverage for 2704 adults with (self-reported) diabetes and 25,008 adults without, using data from the 2009 US National Health Interview Survey. Perhaps surprisingly, they found that coverage by any type of health insurance was higher (90%) in the group with diabetes than in those without (81%). More adults aged 18–64 years with diabetes had Medicare coverage compared to those without (14% vs. 4%), and more of those without diabetes

had private insurance (66% vs. 58%). Those within this age group who had diabetes were more likely to have more than one source of insurance coverage (13% vs. 5%). Songer [24] had commented earlier that 15% of families with one or more children reported difficulty in obtaining health insurance coverage because of pre-existing illness clauses. Casagrande and Cowie's data [23] paints a more optimistic picture for adults.

Some of the consequences, at least in the process of care although not in outcome, of non- and under-insurance are detailed by DeVoe et al. [25]. Their findings, relating to 6562 people with diabetes aged over 18 years and with data (from 2002 to 2005) in the medical Expenditure Panel Survey, were similar to those of Casagrande and Cowie [23] in that more than 84% of people with diabetes had full-year coverage and a USC (usual source of care), and 2.3% had neither coverage nor a USC. However, being uninsured and without a USC was associated with a 5.5-fold higher likelihood of unmet medical needs (compared with being insured and having a USC) and a threefold likelihood of delayed urgent care.

The need for individuals and families in some populations to contribute towards the costs of care is exacerbated by curtailment in earning power as a result of diabetes. Songer [26], commenting on the work of Steen Carlsson et al. [27], has called for "the social consequences of type 1 diabetes [to] … be embraced more frequently in clinical settings." The authors [27] had described similar earning power of people with diabetes and those without diabetes prior to its diagnosis but reduced earnings following diagnosis. With greater than 10 years diabetes duration and controlling for confounders, men with diabetes in employment and with upper secondary education were 4.2% below their nondiabetic peers in annual earnings and women 8.1% below. Songer [26] speculates that "with renewed enthusiasm for the long-term health of individuals after the diagnosis of diabetes [in more recent cohorts of patients], there is hope regarding the potential for full and productive employment."

The financial vulnerability of people with diabetes has also been explored by Schofield et al. [28] and Holmes et al. [29] who have quantified the loss of income not only of people with diabetes but also of their carers. The former, Australian, study concentrated on the economic consequences of taking early retirement as a result of diabetes. The consequences were twofold: loss of income as a result of not being in employment, and reduced accumulated savings to finance their retirement as a result of their diabetes.

The findings of Holmes et al. [29] mirror those of other cost-of-illness studies that have found associations between healthcare costs and the presence of complications in that, although there was loss of earnings for both people with diabetes and their carers throughout the complications spectrum, this was most marked in instances when both micro- and macrocomplications were present. The burden of caring resulted in loss of earnings and significant levels of strain in the carers, as well as loss of earnings and significantly poorer health-related quality of life in the individuals being cared for.

The consequences of less-than-optimum therapy

The efficient use of resources is a topic for the next section of this chapter. The consequences of less than optimum therapy are, however, a useful link between descriptive economic studies and analytical studies such as cost-effectiveness and cost-utility analyses. Brown et al. [30] have examined the cumulative glycemic burden of treatment failure in diabetic members of the Kaiser Permanente Northwest Region Health Maintenance Organization concluding that, even in what was considered (by them) to be a well-controlled population, the average patient accumulated five HbA1c-years of excess glycemic burden compared with target levels and concluded from this that "clinicians should change glucose-lowering treatments in T2DM much sooner or use treatments that are less likely to fail." More recently and also from the US, Nuckols et al. [31] have demonstrated that the cost of improving glucose control to goal (those of the Healthcare Effectiveness Data and Information Set (HEDIS)) being between USD 192 and USD 711 per person, is modest in relation to the extensive overall costs of providing care.

Several large studies have commented on what they consider to be less-than-optimal care. For example, the DiabCare Asia study audited the quality of care in 11 countries in 1998 and 2003 [32] and concluded, from the examination of the records of over 20,000 patients in the first and 15,500 in the second study, that the level of blood glucose control was, in their view, unsatisfactory (mean HbA1c $\approx$ 8% and mean fasting blood glucose $\approx$ 9 mmol L^{-1}). In the Bangladesh component of DiabCare Asia [33], similar conclusions were drawn with a mean HbA1c (amongst 1952 patients) of 8.6% with less than a quarter achieving the American Diabetes Association (ADA) target of <7%.

It is now an accepted tenet of diabetes care that poor metabolic control (not only of blood glucose but also blood pressure and lipids) is associated with an increased likelihood of the development of complications. It is also well known, from the preceding text and other evidence, that complications are associated with higher healthcare costs. If, as suggested by studies such as that of Nuckols et al. [31], improvements in control can be obtained at a modest increase in cost then it is tempting to posit that initiatives to improve control, if successful, will lead eventually to reduced overall costs. However, the difference in the time scale between the short-term increases in costs which are necessary to deliver improved quality of care and the longer time scale for the accrual of economic benefits resulting from the lower incidence of complications means that any reduction in overall costs may, at least in the short term, be elusive. For example, the International Diabetes Management Practice Study (IDMPS) [34], a 27-country initiative aiming to improve the quality of care through enhanced patient education, which significantly improved the proportion achieving metabolic targets, found an increase (though modest) in the cost of care. Any lower incidence of complications resulting from this improvement in care had not, at least at the time of publication, led to a reduction in overall costs.

This phenomenon is not confined to diabetes since the systematic review by Ofman et al. [35] which evaluated 102 studies of managed care for chronic disease (including 22 relating to diabetes) found few studies which convincingly showed a reduction in healthcare costs. This is probably because these initiatives usually lead to no or minimal improvements in clinical outcome or, when minimal improvements are achieved, the resultant cost savings are off-set by increases in the costs of healthcare delivery. The diabetes studies included are now rather dated since they span the years 1986 [36] and 2000 [37]. Amongst these 22 studies, only that of Naji et al. [38] includes a specific economic component though this focuses on additional patient costs, rather than global costs. The more recent systematic review of Knight et al. [39], which was specific to managed care in diabetes, included 24 studies (with considerable overlap with those included by Ofman et al. [35]) but their review concentrated on process and metabolic outcome measures rather than costs. Ofman et al. commented that "although disease management may improve the quality of life for patients with chronic disease [including diabetes], long-term studies may be required to show the economic benefits and financial return on investment." The practicalities of empirical studies with sufficiently long-term follow-up may be such that the most feasible means of examining this question adequately will be modelling studies.

While it is logical to predict that initiatives to improve the quality of care may, in time, reduce the currently substantial costs of providing care to people with diabetes, it is misleading to propose that one of the aims of such initiatives should be to save money. In reality, healthcare resources which are freed up as a consequence of reductions in complications are not "saved" but will, inevitably and logically, be deployed for other purposes. It is not the aim of health systems and it is not the goal of health professionals to save money for the individual, the family, or the state. Rather, the goal is to improve the quality and increase the quantity of life for those affected by diabetes and other long-term conditions through the most effective and efficient use of resources.

The cost effectiveness and cost utility of interventions

Clinicians have a professional obligation to ensure that each patient they are treating receives effective care. They also have an obligation to their other patients that the treatment of that particular patient is as efficient as possible. Ethical clinical care thus requires consideration of both effectiveness and efficiency. Rational health policy making requires consideration of effectiveness, efficiency, and equity. Assessment of all three requires access to the best analytical evidence available.

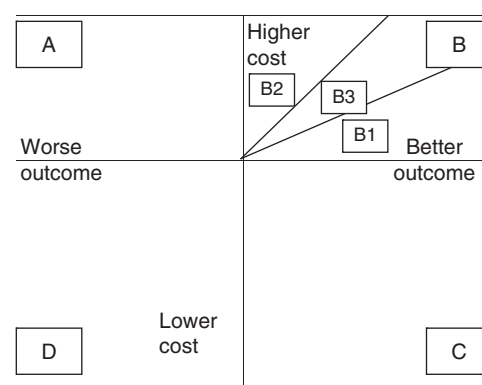
The cost-effectiveness plane
The use of the cost-effectiveness plane as a diagrammatic illustration of the relationships between the costs and effects of


Figure 77.1 The "cost-effectiveness plane."

interventions has been advocated by many, such as Black [40] and Laupacis et al. [41]. In this, two intersecting axes, one relating to cost, the other to effect (or outcome), form four quadrants (Figure 77.1). Quadrant A contains interventions which, in relation to the status quo (the intersection), deliver worse outcome and at higher cost. Clearly these are unacceptable in practice. In B, interventions deliver better outcome but at higher cost — the most commonly encountered case and one in which the acceptability of the intervention in practice will depend on its relative costs and benefits compared with alternatives. In C, interventions are cost saving — better outcome and at lower cost — clearly the most desirable of all while, in D, interventions are less costly but produce worse outcome. As emphasized by Morris et al. [42], the acceptability of interventions in B and D are worth considering in terms of their trade-offs; in B, the extent to which outcome is improved albeit at increased cost; and in D, the extent to which cost is reduced, albeit with worse outcome.

Morris et al. [42] divide zones B and D each into two subzones in which the trade-offs are of contrasting acceptability. Laupacis et al. [41] divide quadrant B into three such subzones (see Figure 77.1): (i) B1, in which interventions are likely to be regarded as cost effective (and, therefore, acceptable) because enhanced effects are achieved at relatively little extra cost; (ii) B2, in contrast, in which only small enhancement of effect requires comparatively large costs — interventions likely to be regarded as unacceptable; and (iii) B2, an intermediate zone in which the acceptability of the interventions will be the subject of debate about the trade-off. Li et al. [43], as described later, split quadrant B into four subzones.

Consideration of interventions falling in zone D raises some subtle questions of the balance between societal gain and individual loss. Particularly in situations where healthcare resources are severely limited, moving to less costly and less effective interventions may well be beneficial to the general population to an extent that mitigates the losses that some individuals will experience as a result of reduced effectiveness. For example, reducing the intensity and/or frequency of screening (perhaps for diabetic eye disease) or increasing the interval between scheduled clinic

visits for routine care will make available healthcare resources which can be used for other activities, either within or without the diabetes field. The resultant benefits of such changes to the general population may outweigh the losses that some individuals experience as a result of late detected retinopathy or other complications.

Comparison of the acceptability of alternative interventions

Economic comparisons of preventive and therapeutic alternatives are of three main types. Cost–benefit analyses identify the various costs of interventions and their potential benefits, assign each of them a monetary value and then compare total costs with total benefits to give a cost/benefit or benefit/cost ratio. The larger the latter (or the smaller the former) the more likely is the intervention to be acceptable. Cost–benefit analyses have the advantage of conceptual simplicity but suffer from the inherent difficulty of assigning valid monetary values particularly to benefits—extended life, reduction of disability or better well-being, for example.

Cost-effectiveness analyses express benefits in "natural units" of, for example, number of cases detected, percentage points of HbA1c reduction, or cases of disability prevented. Such analyses thus circumvent the need to ascribe monetary values to benefits but the main disadvantage of cost-effectiveness analysis is that interventions which lead to different types of benefits cannot be compared. Thus, for example, the cost effectiveness of an intervention aimed at preventing end-stage renal disease (ESRD) cannot be readily compared, using cost-effectiveness analysis, with an intervention aimed at preventing lower limb amputation. It can only be compared with interventions also aimed at ESRD.

Cost-utility analysis uses the concepts of QALYs (quality adjusted life years) or LYGs (life years gained) to provide common units for the comparison of the benefits derived from interventions aimed at different preventive or therapeutic outcomes. The QALY combines the notions of length of life and quality of life and requires assessments of "utility" which people would ascribe to different health states—dependency on renal dialysis versus limblessness, for example.

The incremental cost-effectiveness ratio (ICER) is often used to compare alternatives in cost-utility analysis. This is defined as the ratio between the difference in costs (those of the intervention minus those of an alternative) and the difference in effectiveness (or effects) between the two. The health economic literature (e.g. Morris et al. [42]) devotes considerable attention to the validity of this measure and the nature of alternative interventions for consideration. In practice, however, the usual alternative for comparison is either some form of usual care or treatment with a placebo. Since the aim of improving the effectiveness of interventions is to increase effectiveness at a minimum of increased costs, then the lower the ICER the better. ICERs are usually expressed in terms of cost per QALY or LYG.

What do clinicians and policy makers need to know in terms of analytical studies in diabetes?

It is clearly vital that clinicians and health policy makers have access to high-quality evidence as to which current and potential future interventions, within the epidemiologic and financial contexts in which they function, are cost saving or at least acceptably cost effective. Epidemiologic criteria will be important in respect of, for example, the pre-test probability of a positive result in the early detection of T2DM. This will be influenced by the prevalence of previously undiagnosed T2DM in the population. The local availability of resources will, in part, determine the boundaries between the different trade-off subzones of quadrants B and D in the cost-effectiveness plane.

The areas of practice in which these questions arise may be conveniently divided into three: (i) primary prevention of diabetes, (ii) its early detection (sometimes termed screening), and (iii) clinical management in established diabetes. Issues of cost effectiveness are not the only ones on which healthcare decisions are based. (There will be pragmatic, ethical or, particularly in the case of policy, political influences.) However, issues of cost effectiveness are becoming increasingly well recognized.

What does the recent literature tell us about cost-saving and cost-effective interventions for primary prevention and for managing established diabetes?

The recent, comprehensive review of Li et al. [43] considered interventions to prevent and control diabetes recommended by the ADA in 2008 [44]. English-language publications, from 1985 to May 2008 were reviewed following the protocol of the Cochrane Collaboration [45]. Studies were included only if they were considered "good" or "excellent" according to the *BMJ* authors' guide for economic studies [46]. Interventions were judged according to their ICERs. The strength of evidence in each case was categorized as "strong," "supportive," or "uncertain" according to well-recognized criteria such as those of the Centre for Evidence-Based Medicine at the University of Oxford, and the ADA.

They set boundaries between four zones in quadrant B: (i) very cost effective: ICER ≤ USD 25,000 per QALY or LYG; (ii) cost effective: ICER USD 25,000–50,000; (iii) marginally cost effective: ICER USD 50,001–100,000; and (iv) not cost effective: ICER > USD 100,000. Of the original 9264 titles and abstracts identified, 56 were included in the final data analysis. They found 14 interventions for which strong evidence existed as being cost saving (6 interventions) or very cost effective (8 interventions). These are given in Table 77.2, categorized into the three areas: (i) primary prevention of diabetes (1 intervention); (ii) early detection of diabetes through screening (1); and (iii) clinical management in established diabetes (12).

It is important to note that all of the studies included were conducted in adults and all were based in high-income countries except one [47] from Bangkok, Thailand. This used

Table 77.2 Interventions with "strong evidence" of being cost saving or very cost effective according to Li et al. [43]. For details of primary references, see Table 77.1 of the original review

Intervention	Comparison	Cost saving or very cost effective?	Country setting	Population(s) in which applicable
Primary prevention of diabetes				
Intensive lifestyle modification for the prevention of T2DM among people with impaired glucose tolerance	Standard lifestyle recommendations	Very cost effective	Australia, USA	Overweight and obese adults
Early detection of diabetes				
Population-based screening for undiagnosed T2DM	No screening	Very cost effective	USA	African Americans aged 45–54 years
Clinical management in established diabetes				
ACE-I therapy for the control of hypertension	Standard treatment for hypertension	Cost saving	UK, USA	People with early T2DM and hypertension
ACE-I or angiotensin receptor blocker (ARB) therapy in the prevention of end-stage renal disease	No treatment by ACE-I or ARB	Cost saving	US	People with T2DM and hypertension initially free of CVD and ESRD
Early irbesartan therapy following the advent of microalbuminuria to prevent ESRD	Treatment delayed until macroalbuminuria present	Cost saving	Canada, UK, USA	People with T1 or T2DM and microalbuminuria
Comprehensive foot care to prevent ulceration	Usual care	Cost saving	Sweden	People with T1 or T2DM
Multicomponent intervention* targeted at risk factor control and early detection of complications	Conventional care	Cost saving	Germany, Switzerland, UK, USA	People with T1DM
Multicomponent intervention* targeted at risk factor control and early detection of complications	Conventional care	Cost saving	Germany, Switzerland, UK, USA	People with T2DM
Intensive glycemic control	Standard treatment	Very cost effective**	Japan, Switzerland, UK, USA	People with newly diagnosed T2DM
Statin therapy for secondary prevention of cardiovascular disease	No statin therapy	Very cost effective	Canada, Ireland, UK, USA	People with T2DM and CVD history
Smoking cessation counselling and treatment	Neither	Very cost effective	USA	People with newly diagnosed T2DM who are smokers
Annual screening for retinopathy and ensuing laser treatment	No screening	Very cost effective	Switzerland, USA	People with T1DM
Annual screening for retinopathy and ensuing laser treatment	No screening	Very cost effective	Switzerland, USA	People with T2DM
Immediate vitrectomy for the treatment of retinopathy	Deferred vitrectomy	Very cost effective	USA	People with T1 or T2DM and retinopathy

*Multicomponent intervention, standard antidiabetic care plus education, nephropathy screening, ACE-I treatment and retinopathy screening.

effectiveness data derived from developed countries but, using cost data and survival data from their own country, the authors were able to describe, as cost saving, the use of angiotensin-converting enzyme inhibitors (ACE-I) in slowing the progress of nephropathy in normotensive patients with T2DM and microalbuminuria.

Li et al. [43] commented that "a large majority of the ADA recommended interventions are cost-effective." Their review provides many answers but also raises questions: are the interventions listed in Table 77.2 cost saving or very cost effective in other contexts? Will better evidence recruit more interventions to these categories? Can the efficiency be improved of interventions which they categorize as merely cost effective or marginally cost effective? Those most likely to be acceptable in low- and middle-income countries might be: intensive lifestyle modification for the prevention of T2DM (though this would depend on the degree of intensity required); population-based screening for undiagnosed T2DM in certain ethnic groups within appropriate age bands; comprehensive foot care to prevent ulceration; statin therapy for secondary prevention of cardiovascular disease; smoking cessation counselling and treatment (though this would depend upon the availability of appropriate supportive therapies). The world literature clearly requires periodic assessments of this type but the more immediate need now is for more primary research and subsequent systematic review of interventions which are feasible in low- and middle-income settings.

Narayan and Wilkinson [48], while acknowledging the effectiveness in randomized clinical trials (RCTs) of lifestyle interventions, emphasize the different economic context of prevention programs based in communities in which a large number of participants will be normoglycemic—in whom interventions may be likely to have little impact on future diabetes incidence. Herman [49] has also examined this area, summarizing studies of the cost effectiveness of primary prevention of T2DM—from the USA [50,51], Canada [52], Australia [53], Germany [54], one study from the viewpoints of Australia, France, Germany, Switzerland, and the UK [55], and one from Spain, Germany, and Sweden [56]. All but three of these were included in the review of Li et al. [43]. The exceptions were Herman et al. [50], Icks et al. [54], and Josse et al. [56]. Herman's conclusions [50] are qualitatively similar to those of Li et al. [43], namely, that lifestyle modification as a primary prevention intervention for T2DM is either cost saving [53,55] or extremely cost effective [52,54]. Further, that three of the four published studies that had included metformin in this regard had drawn the same conclusion (the exception being Eddy et al. [51]) and that the two studies including acarbose concluded either that it was cost saving [52] or extremely cost effective [56].

The two reviews cited above and the primary research they summarize all relate to developed countries, settings in which the numbers of people with previously undiagnosed T2DM or prediabetes (impaired glucose regulation outside the diabetic range) although significant, are likely to be lower than in,

for example, the countries of Asia or communities of Asian origin in countries elsewhere. As in developed countries, the within-trial cost effectiveness of interventions for the prevention of T2DM in some of these populations is well established (see, for example, Ramachandran et al. [57]) with lifestyle modification again being the more cost effective compared to metformin. Community-based prevention programmes in populations with a high prevalence of undiagnosed disorders of glucose regulation are likely to be even more cost effective than in populations in, for example, the USA and Western Europe, partly because the costs per case detected will be lower.

In a recent review of all aspects of diabetes in Asian populations, Ramachandran et al. [58] comment that "more data are needed for the economics of diabetes and quality of life and cost-effectiveness of various interventions [in Asian populations]." Particularly valuable would be long-term economic information relevant to community-based primary prevention programmes focusing on whether and to what extent interventions proven to be effective and cost effective in RCTs are cost effective (or even cost saving) in less than ideal settings. While information from empirical studies would be preferable, well-conducted modelling studies would be the "next best thing" given the long-term nature of follow-up and the considerable sample sizes that would be required. Well-conducted modelling studies would maximize the sources of data derived from ethically and socially appropriate empirical sources.

Few aspects of diabetes care generate quite as much controversy as the early detection of (or screening for) T2DM. As listed in Table 77.2, opportunistic screening is regarded as very cost effective in certain high-risk groups. However, for lower risk populations, the current consensus is that it is cost effective as part of a concerted programme for vascular risk assessment, risk reduction, and risk management including both the early detection of both T2DM and lesser degrees of glucose intolerance such as IGT [59,60]. Particularly topical is the question of HbA1c versus blood glucose as the screening test. Though the former is the more costly, its greater predictive value in relation to future complications may make it a cost-effective choice [61].

The information that we have is not what we need most

In 1971 the general practitioner, Julian Tudor Hart, described the "Inverse Care Law" the first part of which is often quoted: "The availability of good medical care tends to vary inversely with the need of the population served" [62]. The currently available literature on the cost effectiveness of interventions to prevent and control diabetes, as illustrated earlier, relates, in the main, to developed countries, yet 80% of the estimated 366 million individuals with diagnosed or undiagnosed diabetes in the world live in low- and middle-income countries [3]. Available knowledge on this important topic, therefore, may be said to illustrate a "law" analogous to the inverse care law—the

"law of the inverse availability of evidence." For prevention and control of diabetes in the majority of the world's populations we have, as yet, insufficient evidence on cost effectiveness. This is ironic given the likelihood that, in these countries, the returns on investment both in economic and human terms (quality of life gained and reduced years of life lost) are likely to be greater per dollar, rupee, pound, peseta, euro, etc. spent than in high-income countries. This follows from the size of the populations concerned, their likely high prevalence of undiagnosed diabetes and their likely large numbers of relatively poorly controlled individuals for whom improvements in control have greater benefits than already close to accepted targets.

The World Bank classifies national economies according to Gross National Income (GNI) per capita [63]. In 2010 prices, the four bands are: (i) high income: USD 12,276 per capita or more; (ii) upper middle income: USD 3976 to USD 12,275; (iii) lower middle income: USD 1006 to USD 3975; (iv) low income: USD 1005 or less. Low-income countries, as judged by these criteria, are listed in Table 77.3. Also illustrated in Table 77.3 are the numbers of people aged 20–74 years estimated to have diabetes, the mean annual diabetes-related expenditure per person and the national prevalence of IGT for each country and for the USA, the country from which most of the cost effectiveness evidence reviewed above is derived.

The number of people with diabetes in these countries for which estimates are available is around 18.5 million. Nine of them have prevalences of IGT comparable with that of the USA. Considerably more is spent per year on each person with diabetes in the USA (USD 8468) than is spent in all of the low-income countries combined (USD 1815) and, as a further measure of inequality, the US expenditure per person per year is 500 times that of the poorest countries (Eritrea, Democratic Republic of Korea, and Myanmar). The IDF Diabetes Atlas [3], from which these data are derived, comments that Luxembourg (not shown in Table 77.3) spends USD 9341 per year for every person with diabetes compared to less than USD 20 in those three poorest countries.

The 37,000 potentially relevant titles identified by search number 1 contained very little information of direct relevance to these low-income countries. An exception is that of Bangladesh which, amongst other topics, has information relevant to the early detection of diabetic neuropathy [64] and nephropathy [65], and the management of the diabetic foot [66]. Given some caution, information from such studies can be extrapolated to other similar contexts. Results from RCTs conducted elsewhere may be combined with local epidemiologic and financial data [47] in modelling studies or, as Baik et al. [67] have observed, locally generated observational data may, under certain circumstances, be of considerable value in providing clinicians and policy makers with information in the absence of locally conducted analytical studies.

As Mbanya [68] commented, in the previous edition of this textbook: "we need studies to explore the feasibility, effectiveness, and cost effectiveness of interventions, particularly brief interventions at primary care settings and of community-wide [preventive] interventions." His remarks were made in the context of sub-Saharan Africa but they are applicable to all developing countries. There have been notable achievements since these words were published but there is still a considerable way to go.

Acknowledgments

I am grateful to Katrina Dalziel and Sue Prosser for assistance with searching the literature and the retrieval of articles.

Figure 3.5 Prevalence of diabetes in men and women in three Arabian countries.

**Figure 3.11** Type 2 diabetes, insulin resistance, and puberty in children.

Figure 11.1 The incretin effect on insulin (a) and glucagon (b) secretion. Following oral administration of nutrients, islet hormone secretion is modulated by (A) the incretin hormones GIP and GLP-1, (B) the sympathetic and parasympathetic nervous system, and (C) the circulating substrates glucose, amino acids, and free fatty acids. Stimulatory actions have been denoted with blue color, inhibitory actions are indicated by red color. Source: Adapted from Creutzfeldt 1979 [98]. Reproduced with permission of Springer.

Figure 12.1 Structural and functional domains of the insulin receptor. Schematic diagram of the insulin receptor showing structural landmarks (left side) and functional domains (right side). (Numbering of amino acids based on translation of the alternatively spliced exon 11.)

Figure 12.2 Metabolic and mitogenic signaling pathways in insulin action. Abbreviations: DAG, diacylglycerol; IP3, inositol-3-phosphates; PI(3,4)P$_2$, phosphatidylinositide 3,4 diphosphate; PI(3,4,5)P$_3$, phosphatidylinositide 3,4,5 triphosphate; PI-3 kinase, phosphatidylinositide-3 kinase; PDK1, phosphoinositide-dependent kinase 1; GSK3, glycogen synthase kinase 3; GS, glycogen synthase; GLUT-4, glucose transport protein 4; IRS, family of insulin receptor substrate proteins; SHIP2, SH2-containing inositol phosphatase 2; Grb2, growth factor receptor bound 2; SOS, mammalian homologue of Drosophila son-of-sevenless protein; Akt/PKB, protein kinase B; Shc, adapter protein with homology with Src and collagen; Ras, rat sarcoma protein; Gap, GTPase activating protein; MAP kinase kinase, mitogen activated protein kinase kinase; MAP kinase, mitogen activating protein kinase; PP1G, glycogen-associated protein phosphatase 1.
Figure 12.3 Three major steps providing for functional divergence of insulin signal transduction. The insulin receptor substrate docking proteins, PI-3 kinase, and Akt/PKB are sequentially activated by insulin, but then each factor engages multiple downstream signal molecules and pathways resulting in divergence, capacity for interaction, and complementarity of insulin signaling pathways. Abbreviations: APS, adaptor protein containing PH and SH2 domains; IRS, insulin receptor substrate protein; Gab-1, GRB-2-associated binding protein 1; Shc, adapter protein with homology with Src and collagen; $PI(3,4,5)P_3$, phosphatidylinositide 3,4,5 triphosphate; mTOR, mammalian target of rapamycin; $p70^{S6K}$, p70 S6 kinase; Akt/PKB, protein kinase B; aPKC, atypical protein kinase C isoforms; GSK3, glycogen synthase kinase-3; BAD, Bcl2 antagonist of cell death; NO, nitric oxide.

Figure 12.4 Two complementary pathways for stimulation of GLUT4 translocation. IRS-1, insulin receptor substrate-1; SHIP2, SH2-containing inositol phosphatase 2; PI-3 kinase, phosphatidylinositide-3 kinase; PKC, protein kinase C; Akt/PKB, protein kinase B; PDK1, phosphoinositide-dependent kinase 1; APS, adaptor protein containing PH and SH2 domains; CAP, c-Cbl associating protein; Cbl, Cbl proto-oncogene; CrkII, Crk oncogene; C3G, guanine nucleotide-releasing protein C3G; TC10, ras-like protein TC10; CIP4/2, Cdc42-interacting protein; GTP, guanosine triphosphate; GDP, guanosine diphosphate.

Figure 12.5 Cellular trafficking and itinerary of GLUT4 glucose transporter proteins. The model is based on a consensus of current data, and includes an endosomal recycling pathway, a separate intracellular inducible GLUT4 storage compartment which supplies the majority of GLUT4 recruited by insulin to the cell surface, and an alternative compartment where accumulated GLUT4 does not respond to insulin in insulin-resistant states (see text).

Figure 12.6 Proteins regulating the docking of exocytotic GLUT4 vesicles at the plasma membrane. Abbreviations: IRAP, insulin regulated aminopeptidase; ACS-1, acyl-CoA synthetase-1; VAMP-2, vesicle-associated membrane protein 2; NSF, N-ethylmaleimide sensitive factor; SNAP-23, soluble NSF attachment 23 kDa protein; Munc-18c, mouse Unc homologue 18c; Synip, syntaxin 4 interacting protein; Rab, monomeric GTPase in the Rab subclass; t-SNARE and v-SNARE refer to target membrane and vesicle-associated soluble N-ethylmaleimide-sensitive attachment protein receptors, respectively.

Figure 12.7 Mechanisms for modulation of insulin signal transduction. The figure illustrates pathways resulting in the desensitization of insulin signal transduction, including serine/threonine phosphorylation of the insulin receptor or IRS by PKC, IKKβ, or JNK; inhibition of the insulin receptor tyrosine kinase by PC-1; tyrosine phosphatase action of PTPase-1B and LAR; catabolism of 3′ phosphoinositide moieties by SHIP-2 or PTEN; inhibition of Akt/PKB activation by ceramide; and interference with substrate binding (STAT5B) to the insulin receptor β subunit by SOCS-3. Abbreviations: PC-1, plasma cell membrane glycoprotein PC-1; SOCS-3, suppressor of cytokine signaling 3; STAT-5B, signal transducer and activator of transcription 5B; PTPase-1B, protein tyrosine phosphatase 1B; LAR, leukocyte antigen-related tyrosine phosphatase; cPKC, classic protein kinase C isoforms; nPKC, novel protein kinase C isoforms; PKC-ζ, protein kinase Cζ; JNK, c-Jun N-terminal kinase; IKK-β, kinase of inhibitor of kappa light chain gene enhancer in B cells β; TNF-α, tumor necrosis factor α; IRS, insulin receptor substrate protein; ser/thr, a serine or threonine residue; Y, tyrosine residue; PI-3 kinase, phosphatidylinositide-3 kinase; SHIP-2, SH2-containing inositol phosphatase 2; PTEN, phosphatase and tensin homologue; Akt/PKB, protein kinase B.

Figure 18.1 Metabolic subdomains of the mammalian metabolome. Analytical protocols using chromatography-coupled mass spectrometry (LC-MS or GC-MS) or proton nuclear magnetic resonance (NMR) are used to simultaneously determine concentrations of metabolites from many metabolic subdomains in urine, blood, or other biofluids. Metabolomics platforms can be either targeted (specific to a metabolite class) or untargeted (more global evaluation of multiple classes in parallel). Source: Kanehisa M, Goto S, Sato Y, Kawashima M, Furumichi M, Tanabe M: Data, information, knowledge and principle: back to metabolism in KEGG. *Nucleic Acids Research* 2014;**42**:D199–D205; Kanehisa M, Goto S: KEGG: Kyoto Encyclopedia of Genes and Genomes. *Nucleic Acids Research* 2000;**28**:27–30.

Figure 22.1 An example of apnea (red), hypopneas (pink), and desaturations (green) in a patient with OSA and T2DM. Note the the presence of thoracic and abdominal movements indicating the presence of obstructive rather than central sleep apnea.

Figure 24.7 Preparation of isolated human islets: (a) the pancreas is distended by the injection of a solution containing the digesting enzymes; (b) this leads to the separation of islets (arrows; the red color is due to dithizone staining) from acinar fragments; (c) islet enrichment is achieved by gradient purification, which can be done manually (as in the panel) or automatically; (d) the final islet preparation (dithizone stained) can be used for *in vitro* studies. Source: Images from PM's laboratory.

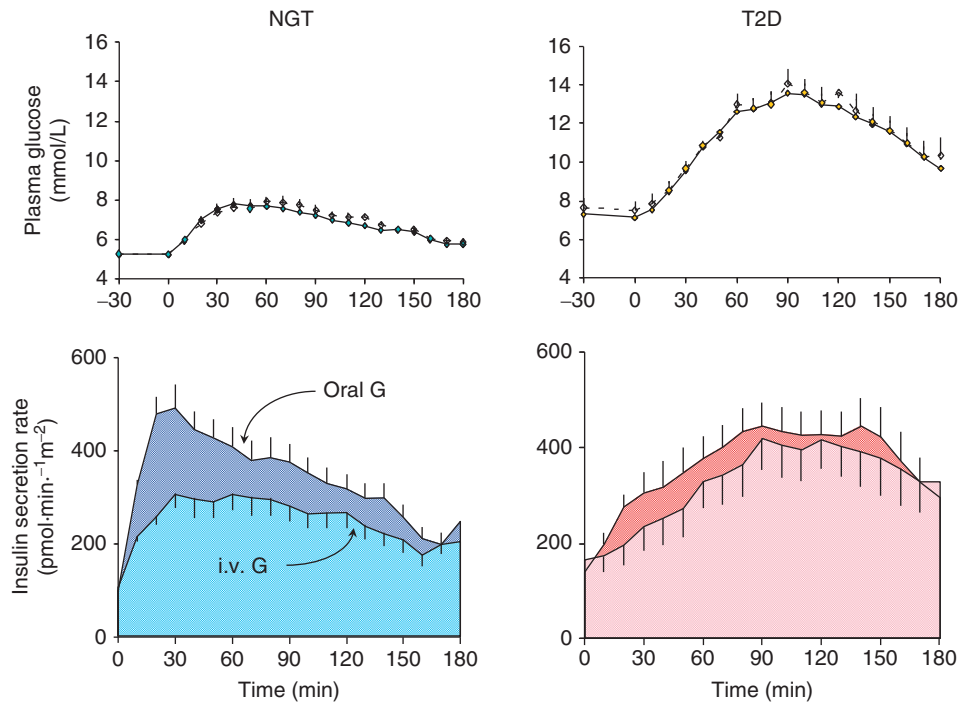
Figure 24.9 DPP-4 is present in human islet cells, co-localizing with glucagon (a), but not with insulin (b) or somatostatin (c).Source: Adapted from Omar et al. 2014 [127]. Reproduced with permission of Springer Science and Business Media.


Figure 24.10 The incretin effect, measured as the difference (dark shaded areas) between the insulin secretory response to oral and intravenous (i.v.) glucose under isoglycemic conditions (top panels). Note the absence of a significant incretin effect in patients with type 2 diabetes (T2D). Source: Redrawn from data in Muscelli et al. 2008 [146].
Figure 24.11 Time-course of glucose-induced and incretin-induced potentiation of insulin secretion in nondiabetic subjects (NGT) and in patients with type 2 diabetes. Source: Redrawn from Tura et al. 2014 [135]. Reproduced with permission of Springer Science and Business Media.
Figure 24.13 Schematic representation of the dedifferentiation concept, according to Wajchenberg 2007 [184]. Under normal conditions, β cells have cytoplasmic FOXO1 (yellow); during metabolic stress, insulin production is maintained (green), with FOXO1 translocating to the nucleus (red) to promote β-cell health. With persisting, FOXO1 expression declines (blue nucleus), other transcription factors are reactivated and insulin production decreases (gray). At this stage, former β cells may revert to an uncommitted endocrine progenitor stage (gray) or undergo conversion to cells producing other hormones (orange).

Brain
↓ Satiety

Liver
↑ Short-chain fatty acids
↑ Inflammation

Gut microbiota
• Altered composition
• Altered fermentation
• Increased energy harvest

Adipose tissue

Epithelium
↑ Permeability of the
  epithelium
↓ PYY/GLP-1 from L-cells

Figure 31.2 Alterations to the composition and metabolic capacity of gut microbiota in obesity promote adiposity and influence metabolic processes in peripheral organs, such as the control of satiety in the brain; the release of hormones from the gut (shown as PYY and GLP-1); and the synthesis, storage or metabolism of lipids in the adipose tissue, liver, and muscle. Microbial molecules also increase intestinal permeability, leading to systemic inflammation and insulin resistance. Source: Tremaroli V, Bäckhed F: *Nature* 2012;**489**(7415):242–249. Reproduced with permission of Nature Publishing Group.

Figure 34.1 (a) Roux-en-Y gastric bypass: the length of the alimentary and biliopancreatic limbs can vary, but the basic design of this procedure results in nutrients moving directly from gastric pouch to post-duodenum small intestine. The relative importance of the effects of duodenal exclusion and increased nutrient exposure to the ileum remains a matter of debate and a focus of much research. (b) Roux-en-Y gastric bypass: the volume of the gastric pouch formed in this procedure can vary.

Figure 34.2 Adjustable gastric band: the pressure applied through the band can be adjusted by injection or withdrawal of solution through the access port.
Figure 34.3 Sleeve gastrectomy: this procedure does not alter the direction of nutrient flow through the gut.
Figure 34.4 Biliopancreatic diversion: the combination of sleeve gastrectomy and intestinal rearrangement results in significant changes to the metabolism, but can result in malabsorption.

Figure 52.6 Comparison of kidney biopsies of native pancreas in type 1 diabetic recipients of pancreas transplantation before, 5 years, and 10 years post-transplant. The increased basement membrane thickness and increased mesangium characteristic of type 1 diabetes that was present pre-transplant was still present at 5 years post-transplant but greatly decreased at 10 years post-transplant. Source: Adapted from Fioretto 1998 [46]. Reproduced with permission of Massachusetts Medical Society.

Figure 53.3 Restoration of symptom responses (main panel) to induced controlled hypoglycemia (top panel) before (blue) and after (orange) a period of strict avoidance of hypoglycemia in daily life. Source: Cranston 1994 [37]. Reproduced with permission of Elsevier.

Figure 53.4 Statistical parametric maps superimposed on MR brain images, showing evolution of changes in regional brain blood flow during experimentally induced hypoglycemia and recovery using water positron emission tomography in healthy volunteers. Blood flow increased (orange) in brain regions involved in stress response, including hypothalamus and pituitary, in symptom perception and awareness including anterior cingulate cortex and in prefrontal regions involved in reward pathways; decreasing (blue) in brain regions involved in balance and memory formation. In the posterior thalamus, flow increased in hypoglycemia and reduced during recovery, the latter perhaps associated with the drowsiness that follows hypoglycemia. Source: Teh et al. [44]. Reproduced with permission of Elsevier.
Figure 63.1 Light microscopic images of sural nerve fascicles from a control subject (a), diabetic patient with minimal (b), moderate (c), and severe (d) neuropathy showing a progressive loss of myelinated fibers (mf) (×300).

**Figure 63.7** Light microscopic image of a sural nerve from a diabetic patient with DLSPN showing epineurial vessel pathology (×500).

Figure 63.8 Light microscopic image of a skin biopsy stained with PGP 9.5 showing normal IENF and dermal fibers (a) and a marked depletion of IENF with only dermal NF in a diabetic patient with neuropathy (b).

Figure 66.1 Infected diabetic foot lesion. A 56-year-old patient presented with a painless, necrotic ulcer on the 5th toe of the left foot. On examination there was surrounding erythema and purulent discharge clinically suggesting infection.

Figure 66.2 Pressure-induced plantar ulceration. This 45-year-old diabetic patient with insensitive feet presented with shoe-induced ulcers on the toes of both feet. The hallux plantar surface showed build-up of callus and there were necrotic lesions on the apices of the 2nd and 3rd toe of the right foot.

Figure 66.3 Thermal foot wound. This 48-year-old female diabetic patient with peripheral neuropathy presented with extensive burns to the plantar surface of the metatarsal head region and hallux caused by walking on hot sand whilst on holiday.
Figure 69.1 Cumulative survival curves for incidence of coronary heart disease (a) and for cardiovascular mortality (b) according to the glucose categories defined by both fasting and 2-h plasma glucose criteria. The cumulative survival are estimated from Cox proportional hazards models and adjusted for age, cohorts, sex, body mass index, blood pressure, serum cholesterol, and smoking. Normal, fasting plasma glucose <6.1 mmol L^1 and 2-h plasma glucose <7.8 mmol L^1; IFG, impaired fasting glycemia only; IGT, impaired glucose tolerance only; IGR, impaired glucose regulation (IFG and IGT); DMF, undiagnosed diabetes by fasting glucose criteria alone (fasting plasma glucose >7.0 mmol L^1 and 2-h plasma glucose <11.1 mmol L^1); DMP, undiagnosed diabetes by 2-h postload glucose criteria alone (2-h plasma glucose ≥11.1 mmol L^1 and fasting plasma glucose <7.0 mmol L^1); DMC, undiagnosed diabetes by both fasting and 2-h glucose criteria combined (fasting plasma glucose ≥7.0 mmol L^1 and 2-h plasma glucose ≥11.1 mmol L^1); known DM, previously diagnosed diabetes.
